#### Unboundedness

# **Basic Equation**

A simple stochastic linear difference equation of the first order in one variable takes the form

 $x_t = ax_{t-1} + \epsilon_t \quad (t \in \mathbb{N})$ 

Here *a* is a real parameter, and each  $\epsilon_t$  is a real random disturbance.

Assume that:

- 1. there is a given or pre-determined initial state  $x_0$ ;
- 2. the random variables  $\epsilon_t$ are independent and identically distributed (IID) with mean  $\mathbb{E}\epsilon_t = 0$  and variance  $\mathbb{E}\epsilon_t^2 = \sigma^2$ .

A special case is when the disturbances are all normally distributed — i.e.,  $\epsilon_t \sim N(0, \sigma^2)$ .

# Explicit Solution and Conditional Mean

For each fixed outcome  $\epsilon^{\mathbb{N}} = (\epsilon_t)_{t \in \mathbb{N}}$  of the random sequence, there is a unique solution which can be written as

$$x_t = a^t x_0 + \sum_{s=1}^t a^{t-s} \epsilon_s$$

The main stable case occurs when |a| < 1.

Then each term of the sum  $a^t x_0 + \sum_{s=1}^t a^{t-s} \epsilon_s$  converges to 0 as  $t \to \infty$ .

This is what econometricians or statisticians call a first-order autoregressive (or AR(1)) process.

In fact, given  $x_0$  at time 0, our assumption that  $\mathbb{E}\epsilon_s = 0$  for all s = 1, 2, ..., timplies that the conditional mean of  $x_t$  is

$$m_t := \mathbb{E}[x_t|x_0] = \mathbb{E}\left[a^t x_0 + \sum_{s=1}^t a^{t-s} \epsilon_s |x_0|\right] = a^t x_0$$

## **Conditional Variance**

The conditional variance, however, is given by

$$v_t := \mathbb{E}\left[(x_t - m_t)^2 | x_0\right] = \mathbb{E}[(x_t - a^t x_0)^2 | x_0] = \mathbb{E}\left[\sum_{s=1}^t a^{t-s} \epsilon_s\right]^2$$

In the case we are considering with independently distributed disturbances  $\epsilon_s$ , the variance of a sum is the sum of the variances.

١

Hence, because each  $\mathbb{E}\epsilon_s = 0$ , one has

$$\mathbf{v}_t = \sum_{s=1}^t \mathbb{E} \left[ a^{t-s} \epsilon_s \right]^2 = \sum_{s=1}^t a^{2(t-s)} \mathbb{E} \epsilon_s^2 = \sigma^2 \sum_{s=1}^t a^{2(t-s)}$$

Using the rule for summing the geometric series  $\sum_{s=1}^{t} a^{2(t-s)}$ , we finally obtain

$$\nu_t = \frac{1 - a^{2t}}{1 - a^2} \sigma^2$$

# Sums of Normally Distributed Random Variables, I

Recall that if  $X \sim N(\mu, \sigma^2)$ , then the characteristic function defined by  $\phi_X(t) = \mathbb{E}[e^{iXt}]$  takes the form

$$\phi_X(t) = \mathbb{E}[e^{iXt}] = \int_{-\infty}^{+\infty} e^{ixt} \frac{1}{\sqrt{2\pi\sigma^2}} \exp{-\frac{1}{2} \left(\frac{x-\mu}{\sigma}\right)^2} dx$$

This reduces to  $\phi_X(t) = \exp\left(it\mu - \frac{1}{2}\sigma^2 t^2\right)$ .

Hence, if Z = X + Y where  $X \sim N(\mu_X, \sigma_X^2)$  and  $Y \sim N(\mu_Y, \sigma_Y^2)$  are independent random, variables, then

$$\phi_{Z}(t) = \mathbb{E}[e^{iZt}] = \mathbb{E}[e^{i(X+Y)t}] = \mathbb{E}[e^{iXt}e^{iYt}] = \mathbb{E}[e^{iXt}]\mathbb{E}[e^{iYt}]$$

University of Warwick, EC9A0 Maths for Economists, Day 10

Sums of Normally Distributed Random Variables, II So

$$\phi_Z(t) = \exp\left(it\mu_X - \frac{1}{2}\sigma_X^2 t^2\right) \exp\left(it\mu_Y - \frac{1}{2}\sigma_Y^2 t^2\right)$$
  
= 
$$\exp\left(it(\mu_X + \mu_Y) - \frac{1}{2}(\sigma_X^2 + \sigma_Y^2)t^2\right)$$
  
= 
$$\exp\left(it\mu_Z - \frac{1}{2}\sigma_Z^2 t^2\right)$$

where  $\mu_Z = \mu_X + \mu_Y = \mathbb{E}(X + Y)$  is the mean of X + Y, and  $\sigma_Z^2 = \sigma_X^2 + \sigma_Y^2$  is the variance of X + Y. It follows that  $t \mapsto \phi_Z(t)$ is the characteristic function of a random variable  $Z \sim N(\mu_Z, \sigma_Z^2)$ where  $\mu_Z = \mu_X + \mu_Y = \mathbb{E}(X + Y)$  and  $\sigma_Z^2 = \sigma_X^2 + \sigma_Y^2$ .

That is, the sum Z = X + Y

of two independent normally distributed random variables X and Y is also normally distributed, with:

- 1. mean equal to the sum of the means;
- 2. variance equal to the sum of the variances.

# The Gaussian Case and the Asymptotic Distribution

In the particular case when each  $\epsilon_t$  is normally distributed as well as IID, then  $x_t$  is also normally distributed with mean  $m_t$  and variance  $v_t$ .

As  $t \to \infty$ , the conditional mean  $m_t = a^t x_0 \to 0$ and the conditional variance

$$v_t = rac{1-a^{2t}}{1-a^2}\sigma^2 o v := rac{\sigma^2}{1-a^2}$$

In the case when each  $\epsilon_t$  is normally distributed, this implies that the asymptotic distribution of  $x_t$  is also normal, with mean 0 and variance  $v = \sigma^2/(1 - a^2)$ .

# Stationarity

Now suppose that  $x_0$  itself has this asymptotic normal distribution — that is, suppose that  $x_0 \sim N(0, \sigma^2/(1-a^2))$ .

This is what the distribution of  $x_0$  would be if the process had started at  $t = -\infty$  instead of at t = 0.

Then the unconditional mean of each  $x_t$  is  $\mathbb{E}x_t = a^t \mathbb{E}x_0 = 0$ .

On the other hand, because  $x_{t+k} = a^k x_t + \sum_{s=1}^k a^{k-s} \epsilon_{t+s}$ , the unconditional covariance of  $x_t$  and  $x_{t+k}$  is

$$\mathbb{E}(x_{t+k}x_t) = \mathbb{E}[a^k x_t^2] = a^k v = \frac{a^k}{1-a^2}\sigma^2 \quad (k = 0, 1, 2...)$$

In fact, given any t, the joint distribution of the r random variables  $x_t, x_{t+1}, \ldots, x_{t+r-1}$ is multivariate normal with variance-covariance matrix having elements  $\mathbb{E}(x_{t+k}x_t) = a^k \sigma^2/(1-a^2)$ , independent of t.

Because of this independence, the process is said to be stationary.

## Intertemporal Utility

Consider a household which at time *s* is planning its intertemporal consumption stream  $\mathbf{c}_s^T := (c_s, c_{s+1}, \dots, c_T)$ over periods *t* in the set  $\{s, s + 1, \dots, T\}$ .

Its intertemporal utility function  $\mathbb{R}^{T-s+1} \ni \mathbf{c}_s^T \mapsto U_s^T(\mathbf{c}_s^T) \in \mathbb{R}$ is assumed to take the additively separable form

$$U_s^T(\mathbf{c}_s^T) := \sum_{t=s}^T u_t(c_t)$$

where the one period felicity functions  $c \mapsto u_t(c)$ are differentiably increasing and strictly concave (DISC) — i.e.,  $u'_t(c) > 0$ , and  $u''_t(c) < 0$  for all t and all c > 0.

Suppose the household faces:

- 1. fixed initial wealth  $w_s$ ;
- 2. a terminal wealth constraint  $w_{T+1} \ge 0$ .

# Risky Wealth Accumulation

We assume a wealth accumulation equation  $w_{t+1} = \tilde{r}_t(w_t - c_t)$ , where  $\tilde{r}_t$  is the household's gross rate of return on its wealth in period t.

It is assumed that:

- 1. the return  $\tilde{r}_t$  in each period t is a random variable with positive values;
- the return distributions for different times t are stochastically independent;
- starting with predetermined wealth w<sub>s</sub> at time s, the household seeks to maximize the expectation E<sub>s</sub>[U<sub>s</sub><sup>T</sup>(c<sub>s</sub><sup>T</sup>)] of its intertemporal utility.

## Two Period Case

We work backwards from the last period, when s = T.

In this last period the household will obviously choose  $c_T = w_T$ , yielding a maximized utility equal to  $V_T(w_T) = u_T(w_T)$ .

Next, consider the penultimate period, when s = T - 1. The consumer will want to choose  $c_{T-1}$  in order to maximize

$$\underbrace{u_{T-1}(c_{T-1})}_{\text{period }T-1} + \underbrace{\mathbb{E}_{T-1}V_T(w_T)}_{\text{result of an optimal policy in period }T}$$

subject to the wealth constraint

# First-Order Condition

Substituting both the function  $V_T(w_T) = u_T(w_T)$ and the wealth constraint into the objective reduces the problem to

$$\max_{c_{\tau-1}} \{ u_{\tau-1}(c_{\tau-1}) + \mathbb{E}_{\tau-1} [ u_{\tau}(\tilde{r}_{\tau-1}(w_{\tau-1}-c_{\tau-1})) ] \}$$

subject to  $0 \le c_{T-1} \le w_{T-1}$  and  $\tilde{c}_T := \tilde{r}_{T-1}(w_{T-1} - c_{T-1})$ . Assume we can differentiate under the integral sign, and that there is an interior solution with  $0 < c_{T-1} < w_{T-1}$ . Then the first-order condition (FOC) is

$$0 = u'_{T-1}(c_{T-1}) + \mathbb{E}_{T-1}[(-\tilde{r}_{T-1})u'_{T}(\tilde{r}_{T-1}(w_{T-1}-c_{T-1}))]$$

University of Warwick, EC9A0 Maths for Economists, Day 10

# The Stochastic Euler Equation

Rearranging the first-order condition while recognizing that  $\tilde{c}_T := \tilde{r}_{T-1}(w_{T-1} - c_{T-1})$ , one obtains

$$u'_{T-1}(c_{T-1}) = \mathbb{E}_{T-1}[\tilde{r}_{T-1}u'_{T}(\tilde{r}_{T-1}(w_{T-1}-c_{T-1}))]$$

Dividing by  $u'_{T-1}(c_{T-1})$  gives the stochastic Euler equation

$$1 = \mathbb{E}_{\tau-1}\left[\tilde{r}_{\tau-1}\frac{u_{\tau}'(\tilde{c}_{\tau})}{u_{\tau-1}'(c_{\tau-1})}\right] = \mathbb{E}_{\tau-1}\left[\tilde{r}_{\tau-1}\mathsf{MRS}_{\tau-1}^{\tau}(c_{\tau-1};\tilde{c}_{\tau})\right]$$

involving the marginal rate of substitution function

$$\mathsf{MRS}_{\mathcal{T}-1}^{\mathcal{T}}(c_{\mathcal{T}-1};\tilde{c}_{\mathcal{T}}) := \frac{u_{\mathcal{T}}'(\tilde{c}_{\mathcal{T}})}{u_{\mathcal{T}-1}'(c_{\mathcal{T}-1})}$$

# The CES Case

For the marginal utility function  $c \mapsto u'(c)$ , its elasticity of substitution is defined for all c > 0 by  $\eta(c) := d \ln u'(c)/d \ln c$ .

Then  $\eta(c)$  is both the degree of relative risk aversion, and the degree of relative fluctuation aversion.

A constant elasticity of substitution (or CES) utility function satisfies  $d \ln u'(c)/d \ln c = -\epsilon < 0$  for all c > 0.

The marginal rate of substitution satisfies  $u'(c)/u'(\bar{c}) = (c/\bar{c})^{-\epsilon}$  for all  $c, \bar{c} > 0$ .

## Normalized Utility

Normalize by putting u'(1) = 1, implying that  $u'(c) \equiv c^{-\epsilon}$ .

Then integrating gives

$$u(c;\epsilon) = u(1) + \int_{1}^{c} x^{-\epsilon} dx$$
  
= 
$$\begin{cases} u(1) + \frac{c^{1-\epsilon} - 1}{1-\epsilon} & \text{if } \epsilon \neq 1 \\ u(1) + \ln c & \text{if } \epsilon = 1 \end{cases}$$

Introduce the final normalization

$$u(1) = \begin{cases} \frac{1}{1-\epsilon} & \text{if } \epsilon \neq 1 \\ 0 & \text{if } \epsilon = 1 \end{cases}$$

The utility function is reduced to

$$u(c;\epsilon) = egin{cases} rac{c^{1-\epsilon}}{1-\epsilon} & ext{if } \epsilon 
eq 1 \ \ln c & ext{if } \epsilon = 1 \end{cases}$$

# The Stochastic Euler Equation in the CES Case

Consider the CES case when  $u'_t(c) \equiv \delta_t c^{-\epsilon}$ , where each  $\delta_t$  is the discount factor for period t.

### Definition

The one-period discount factor in period t is defined as  $\beta := \delta - \frac{1}{\delta}$ 

is defined as 
$$\beta_t := \delta_{t+1}/\delta_t$$
.

Then the stochastic Euler equation takes the form

$$1 = \mathbb{E}_{\tau-1} \left[ \tilde{r}_{\tau-1} \beta_{\tau-1} \left( \frac{\tilde{c}_{\tau}}{c_{\tau-1}} \right)^{-\epsilon} \right]$$

Because  $c_{T-1}$  is being chosen at time T-1, this implies that

$$(c_{T-1})^{-\epsilon} = \mathbb{E}_{T-1} \left[ \tilde{r}_{T-1} \beta_{T-1} (\tilde{c}_T)^{-\epsilon} \right]$$

### The Two Period Problem in the CES Case

In the two-period case, we know that

$$\tilde{c}_T = \tilde{w}_T = \tilde{r}_{T-1}(w_{T-1} - c_{T-1})$$

in the last period, so the Euler equation becomes

$$(c_{\mathcal{T}-1})^{-\epsilon} = \mathbb{E}_{\mathcal{T}-1} \left[ \tilde{r}_{\mathcal{T}-1} \beta_{\mathcal{T}-1} (\tilde{c}_{\mathcal{T}})^{-\epsilon} \right]$$
  
=  $\beta_{\mathcal{T}-1} (w_{\mathcal{T}-1} - c_{\mathcal{T}-1})^{-\epsilon} \mathbb{E}_{\mathcal{T}-1} \left[ (\tilde{r}_{\mathcal{T}-1})^{1-\epsilon} \right]$ 

Take the  $(-1/\epsilon)$  th power of each side and define

$$\rho_{\mathcal{T}-1} := \left(\beta_{\mathcal{T}-1} \mathbb{E}_{\mathcal{T}-1} \left[ \left( \tilde{r}_{\mathcal{T}-1} \right)^{1-\epsilon} \right] \right)^{-1/\epsilon}$$

This reduces the Euler equation to  $c_{T-1} = \rho_{T-1}(w_{T-1} - c_{T-1})$ . Its solution is evidently  $c_{T-1} = \gamma_{T-1}w_{T-1}$  where

$$\gamma_{\mathcal{T}-1} := \rho_{\mathcal{T}-1} / (1 + \rho_{\mathcal{T}-1})$$
 and  $1 - \gamma_{\mathcal{T}-1} = 1 / (1 + \rho_{\mathcal{T}-1})$ 

are respectively the optimal consumption and savings ratios. It follows that  $\rho_{T-1} = \gamma_{T-1}/(1 - \gamma_{T-1})$  is the consumption/savings ratio.

University of Warwick, EC9A0 Maths for Economists, Day 10

# Optimal Discounted Expected Utility

The optimal policy in periods T and T - 1is  $c_t = \gamma_t w_t$  where  $\gamma_T = 1$  and  $\gamma_{T-1}$  has just been defined.

In this CES case, the discounted utility of consumption in period T is  $V_T(w_T) := \delta_T u(w_T; \epsilon)$ .

The discounted expected utility at time T-1 of consumption in periods T and T-1 together is

$$V_{\mathcal{T}-1}(w_{\mathcal{T}-1}) = \delta_{\mathcal{T}-1} u(\gamma_{\mathcal{T}-1} w_{\mathcal{T}-1}; \epsilon) + \delta_{\mathcal{T}} \mathbb{E}_{\mathcal{T}-1}[u(\tilde{w}_{\mathcal{T}}; \epsilon)]$$

where  $\tilde{w}_T = \tilde{r}_{T-1}(1 - \gamma_{T-1})w_{T-1}$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

24 of 86

### Discounted Expected Utility in the Logarithmic Case

In the logarithmic case when  $\epsilon = 1$ , one has

$$V_{\mathcal{T}-1}(w_{\mathcal{T}-1}) = \delta_{\mathcal{T}-1} \ln(\gamma_{\mathcal{T}-1}w_{\mathcal{T}-1}) \\ + \delta_{\mathcal{T}}\mathbb{E}_{\mathcal{T}-1}[\ln(\tilde{r}_{\mathcal{T}-1}(1-\gamma_{\mathcal{T}-1})w_{\mathcal{T}-1})]$$

It follows that

$$V_{\mathcal{T}-1}(w_{\mathcal{T}-1}) = \alpha_{\mathcal{T}-1} + (\delta_{\mathcal{T}-1} + \delta_{\mathcal{T}})u(w_{\mathcal{T}-1};\epsilon)$$

where

$$\alpha_{\mathcal{T}-1} := \delta_{\mathcal{T}-1} \ln \gamma_{\mathcal{T}-1} + \delta_{\mathcal{T}} \left\{ \ln(1-\gamma_{\mathcal{T}-1}) + \mathbb{E}_{\mathcal{T}-1} [\ln \tilde{r}_{\mathcal{T}-1}] \right\}$$

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

25 of 86

# Discounted Expected Utility in the CES Case

In the CES case when  $\epsilon \neq 1$ , one has

$$(1-\epsilon)V_{\tau-1}(w_{\tau-1}) = \delta_{\tau-1}(\gamma_{\tau-1}w_{\tau-1})^{1-\epsilon} + \delta_{\tau}[(1-\gamma_{\tau-1})w_{\tau-1}]^{1-\epsilon} \mathbb{E}_{\tau-1}[(\tilde{r}_{\tau-1})^{1-\epsilon}]$$

so 
$$V_{T-1}(w_{T-1}) = v_{T-1}u(w_{T-1}; \epsilon)$$
 where  
 $v_{T-1} := \delta_{T-1}(\gamma_{T-1})^{1-\epsilon} + \delta_T(1-\gamma_{T-1})^{1-\epsilon} \mathbb{E}_{T-1}[(\tilde{r}_{T-1})^{1-\epsilon}]$ 

In both cases, one can write  $V_{T-1}(w_{T-1}) = \alpha_{T-1} + v_{T-1}u(w_{T-1}; \epsilon)$ for a suitable additive constant  $\alpha_{T-1}$  (which is 0 in the CES case) and a suitable multiplicative constant  $v_{T-1}$ .

Finite Horizon Case Infinite Time Horizon Stationarity and the Bellman Equation Finding a Fixed Function Successive Approximation and Policy Improvement

#### Unboundedness

University of Warwick, EC9A0 Maths for Economists, Day 10

# The Time Line

In each period *t*, suppose:

- the consumer starts with known wealth w<sub>t</sub>;
- then the consumer chooses consumption c<sub>t</sub>, along with savings or residual wealth w<sub>t</sub> - c<sub>t</sub>;
- ► there is a cumulative distribution function F<sub>t</sub>(r) on ℝ that determines the gross return r̃<sub>t</sub> as a positive-valued random variable.

After these three steps have been completed, the problem starts again in period t + 1, with the consumer's wealth known to be  $w_{t+1} = \tilde{r}_t(w_t - c_t)$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

# Expected Conditionally Expected Utility

Starting at any t, suppose the consumer's choices, together with the random returns, jointly determine a cdf  $F_t^T$  over the space of intertemporal consumption streams  $\mathbf{c}_t^T$ .

The associated expected utility is  $\mathbb{E}_t \left[ U_t^T (\mathbf{c}_t^T) \right]$ , using the shorthand  $\mathbb{E}_t$  to denote integration w.r.t. the cdf  $F_t^T$ .

Then, given that the consumer has chosen  $c_t$  at time t, let  $\mathbb{E}_{t+1}[\cdot|c_t]$  denote the conditional expected utility.

This is found by integrating w.r.t. the conditional cdf  $F_{t+1}^T(\mathbf{c}_{t+1}^T|c_t)$ .

The law of iterated expectations allows us to write the unconditional expectation  $\mathbb{E}_t \left[ U_t^T(\mathbf{c}_t^T) \right]$ 

as the expectation  $\mathbb{E}_t[\mathbb{E}_{t+1}[U_t^{\mathsf{T}}(\mathbf{c}_t^{\mathsf{T}})|c_t]]$  of the conditional expectation.

# The Expectation of Additively Separable Utility

Our hypothesis is that the intertemporal von Neumann–Morgenstern utility function takes the additively separable form

$$U_t^T(\mathbf{c}_t^T) = \sum_{\tau=t}^T u_{\tau}(c_{\tau})$$

The conditional expectation given  $c_t$  must then be

$$\mathbb{E}_{t+1}[U_t^{\mathsf{T}}(\mathbf{c}_t^{\mathsf{T}})|c_t] = u_t(c_t) + \mathbb{E}_{t+1}\left[\sum_{\tau=t+1}^{\mathsf{T}} u_{\tau}(c_{\tau})|c_t\right]$$

whose expectation is

$$\mathbb{E}_t\left[\sum\nolimits_{\tau=t}^{T} u_{\tau}(c_{\tau})\right] = u_t(c_t) + \mathbb{E}_t\left[\mathbb{E}_{t+1}\left[\sum\nolimits_{\tau=t+1}^{T} u_{\tau}(c_{\tau})\right] | c_t\right]$$

# The Continuation Value

Let  $V_{t+1}(w_{t+1})$  be the state valuation function expressing the maximum of the continuation value

$$\mathbb{E}_{t+1}\left[U_{t+1}^{\mathsf{T}}(\mathbf{c}_{t+1}^{\mathsf{T}})|w_{t+1}\right] = \mathbb{E}_{t+1}\left[\sum_{\tau=t+1}^{\mathsf{T}} u_{\tau}(c_{\tau})|w_{t+1}\right]$$

as a function of the wealth level or state  $w_{t+1}$ .

Assume this maximum value is achieved by following an optimal policy from period t + 1 on.

Then total expected utility at time t will then reduce to

$$\mathbb{E}_t \left[ U_t^T (\tilde{\mathbf{c}}_t^T) | c_t \right] = u_t(c_t) + \mathbb{E}_t \left[ \mathbb{E}_{t+1} \left[ \sum_{\tau=t+1}^T u_\tau(c_\tau) | w_{t+1} \right] | c_t \right] \\ = u_t(c_t) + \mathbb{E}_t [V_{t+1}(\tilde{w}_{t+1}) | c_t] \\ = u_t(c_t) + \mathbb{E}_t [V_{t+1}(\tilde{r}_t(w_t - c_t))]$$

# The Principle of Optimality

Maximizing  $\mathbb{E}_s \left[ U_s^T (\mathbf{c}_s^T) \right]$  w.r.t.  $c_s$ , taking as fixed the optimal consumption plans  $c_t(w_t)$  at times  $t = s + 1, \ldots, T$ , therefore requires choosing  $c_s$  to maximize

$$u_s(c_s) + \mathbb{E}_s[V_{s+1}(\tilde{r}_s(w_s - c_s))]$$

Let  $c_s^*(w_s)$  denote a solution to this maximization problem.

Then the value of an optimal plan  $(c_t^*(w_t))_{t=s}^T$ that starts with wealth  $w_s$  at time s is

$$V_{s}(w_{s}) := u_{s}(c_{s}^{*}(w_{s})) + \mathbb{E}_{s}[V_{s+1}(\tilde{r}_{s}(w_{s} - c_{s}^{*}(w_{s})))]$$

Together, these two properties can be expressed as

$$\begin{array}{lll} V_{s}(w_{s}) & = \\ c_{s}^{*}(w_{s}) & = \end{array} \end{array} \\ \max_{0 \leq c_{s} \leq w_{s}} \left\{ u_{s}(c_{s}) + \mathbb{E}_{s}[V_{s+1}(\tilde{r}_{s}(w_{s}-c_{s}))] \right\} \end{array}$$

which can be described as the the principle of optimality.

# An Induction Hypothesis

Consider once again the case when  $u_t(c) \equiv \delta_t u(c; \epsilon)$ for the CES (or logarithmic) utility function that satisfies  $u'(c; \epsilon) \equiv c^{-\epsilon}$  and, specifically

$$u(c;\epsilon) = egin{cases} c^{1-\epsilon}/(1-\epsilon) & ext{if } \epsilon 
eq 1; \ \ln c & ext{if } \epsilon = 1. \end{cases}$$

Inspired by the solution we have already found for the final period T and penultimate period T - 1, we adopt the induction hypothesis that there are constants  $\alpha_t, \gamma_t, v_t$   $(t = T, T - 1, \dots, s + 1, s)$  for which

$$c_t^*(w_t) = \gamma_t w_t$$
 and  $V_t(w_t) = lpha_t + v_t u(w_t; \epsilon)$ 

In particular, the consumption ratio  $\gamma_t$  and savings ratio  $1 - \gamma_t$  are both independent of the wealth level  $w_t$ .

### Applying Backward Induction

Under the induction hypotheses that

$$c_t^*(w_t) = \gamma_t w_t$$
 and  $V_t(w_t) = \alpha_t + v_t u(w_t; \epsilon)$ 

the maximand

$$u_s(c_s) + \mathbb{E}_s[V_{s+1}(\tilde{r}_s(w_s - c_s))]$$

takes the form

$$\delta_{s}u(c_{s};\epsilon) + \mathbb{E}_{s}[\alpha_{s+1} + v_{s+1}u(\tilde{r}_{s}(w_{s} - c_{s});\epsilon)]$$

The first-order condition for this to be maximized w.r.t.  $c_s$  is

$$0 = \delta_s u'(c_s; \epsilon) - v_{s+1} \mathbb{E}_s[\tilde{r}_s u'(\tilde{r}_s(w_s - c_s); \epsilon)]$$

or, equivalently, that

$$\delta_s(c_s)^{-\epsilon} = v_{s+1}\mathbb{E}_s[\tilde{r}_s(\tilde{r}_s(w_s - c_s))^{-\epsilon})] = v_{s+1}(w_s - c_s)^{-\epsilon}\mathbb{E}_s[(\tilde{r}_s)^{1-\epsilon}]$$

# Solving the Logarithmic Case

When  $\epsilon = 1$  and so  $u(c; \epsilon) = \ln c$ , the first-order condition reduces to  $\delta_s(c_s)^{-1} = v_{s+1}(w_s - c_s)^{-1}$ . Its solution is indeed  $c_s = \gamma_s w_s$  where  $\delta_s(\gamma_s)^{-1} = v_{s+1}(1 - \gamma_s)^{-1}$ , implying that  $\gamma_s = \delta_s / (\delta_s + v_{s+1})$ .

The state valuation function then becomes

$$V_{s}(w_{s}) = \delta_{s} u(\gamma_{s} w_{s}; \epsilon) + \alpha_{s+1} + v_{s+1} \mathbb{E}_{s}[u(\tilde{r}_{s}(1-\gamma_{s})w_{s}; \epsilon)]$$
  
=  $\delta_{s} \ln(\gamma_{s} w_{s}) + \alpha_{s+1} + v_{s+1} \mathbb{E}_{s}[\ln(\tilde{r}_{s}(1-\gamma_{s})w_{s})]$   
=  $\delta_{s} \ln(\gamma_{s} w_{s}) + \alpha_{s+1} + v_{s+1} \{\ln(1-\gamma_{s})w_{s} + \ln R_{s}\}$ 

where we define the geometric mean certainty equivalent return  $R_s$  so that  $\ln R_s := \mathbb{E}_s[\ln(\tilde{r}_s)]$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

# The State Valuation Function

The formula

$$V_s(w_s) = \delta_s \ln(\gamma_s w_s) + \alpha_{s+1} + v_{s+1} \{ \ln(1 - \gamma_s) w_s + \ln R_s \}$$

reduces to the desired form  $V_s(w_s) = \alpha_s + v_s \ln w_s$ provided we take  $v_s := \delta_s + v_{s+1}$ , which implies that  $\gamma_s = \delta_s / v_s$ , and also

$$\begin{aligned} \alpha_{s} &:= \delta_{s} \ln \gamma_{s} + \alpha_{s+1} + v_{s+1} \{ \ln(1 - \gamma_{s}) + \ln R_{s} \} \\ &= \delta_{s} \ln(\delta_{s}/v_{s}) + \alpha_{s+1} + v_{s+1} \{ \ln(v_{s+1}/v_{s}) + \ln R_{s} \} \\ &= \delta_{s} \ln \delta_{s} + \alpha_{s+1} - v_{s} \ln v_{s} + v_{s+1} \{ \ln v_{s+1} + \ln R_{s} \} \end{aligned}$$

This confirms the induction hypothesis for the logarithmic case. The relevant constants  $v_s$  are found by summing backwards, starting with  $v_T = \delta_T$ , implying that  $v_s = \sum_{\tau=s}^T \delta_s$ .

# The Stationary Logarithmic Case

In the stationary logarithmic case:

 the felicity function in each period t is β<sup>t</sup> ln c<sub>t</sub>, so the one period discount factor is the constant β;

▶ the certainty equivalent return  $R_t$  is also a constant R. Then  $v_s = \sum_{\tau=s}^{T} \delta_s = \sum_{\tau=s}^{T} \beta^{\tau} = (\beta^s - \beta^{T+1})/(1 - \beta)$ , implying that  $\gamma_s = \beta^s/v_s = \beta^s(1 - \beta)/(\beta^s - \beta^{T+1})$ .

It follows that

$$c_s = \gamma_s w_s = \frac{(1-\beta)w_s}{1-\beta^{T-s+1}} = \frac{(1-\beta)w_s}{1-\beta^{H+1}}$$

when there are H := T - s periods left before the horizon T.

As  $H \to \infty$ , this solution converges to  $c_s = (1 - \beta)w_s$ , so the savings ratio equals the constant discount factor  $\beta$ . Remarkably, this is also independent of the gross return to saving.

### First-Order Condition in the CES Case

Recall that the first-order condition in the CES Case is

$$\delta_s(c_s)^{-\epsilon} = v_{s+1}(w_s - c_s)^{-\epsilon} \mathbb{E}_s[(\tilde{r}_s)^{1-\epsilon}] = v_{s+1}(w_s - c_s)^{-\epsilon} R_s^{1-\epsilon}$$

where we have defined the certainty equivalent return  $R_s$  as the solution to  $R_s^{1-\epsilon} := \mathbb{E}_s[(\tilde{r}_s)^{1-\epsilon}].$ 

The first-order condition indeed implies that  $c_s^*(w_s) = \gamma_s w_s$ , where  $\delta_s(\gamma_s)^{-\epsilon} = v_{s+1}(1-\gamma_s)^{-\epsilon} R_s^{1-\epsilon}$ .

This implies that

$$\frac{\gamma_s}{1-\gamma_s} = \left( v_{s+1} R_s^{1-\epsilon} / \delta_s \right)^{-1/\epsilon}$$

or

$$\gamma_{s} = \frac{\left(v_{s+1}R_{s}^{1-\epsilon}/\delta_{s}\right)^{-1/\epsilon}}{1 + \left(v_{s+1}R_{s}^{1-\epsilon}/\delta_{s}\right)^{-1/\epsilon}} = \frac{\left(v_{s+1}R_{s}^{1-\epsilon}\right)^{-1/\epsilon}}{\left(\delta_{s}\right)^{-1/\epsilon} + \left(v_{s+1}R_{s}^{1-\epsilon}\right)^{-1/\epsilon}}$$

## Completing the Solution in the CES Case

Under the induction hypothesis that  $V_{s+1}(w) = v_{s+1}w^{1-\epsilon}/(1-\epsilon)$ , one also has

$$(1-\epsilon)V_s(w_s) = \delta_s(\gamma_s w_s)^{1-\epsilon} + v_{s+1}\mathbb{E}_s[(\tilde{r}_s(1-\gamma_s)w_s)^{1-\epsilon}]$$

This reduces to the desired form  $(1-\epsilon)V_s(w_s) = v_s(w_s)^{1-\epsilon}$ , where

$$\begin{split} v_{s} &:= \delta_{s}(\gamma_{s})^{1-\epsilon} + v_{s+1} \mathbb{E}_{s}[(\tilde{r}_{s})^{1-\epsilon}](1-\gamma_{s})^{1-\epsilon} \\ &= \frac{\delta_{s}(v_{s+1}R_{s}^{1-\epsilon})^{1-1/\epsilon} + v_{s+1}R_{s}^{1-\epsilon}(\delta_{s})^{1-1/\epsilon}}{[(\delta_{s})^{-1/\epsilon} + (v_{s+1}R_{s}^{1-\epsilon})^{-1/\epsilon}]^{1-\epsilon}} \\ &= \delta_{s}v_{s+1}R_{s}^{1-\epsilon}\frac{(v_{s+1}R_{s}^{1-\epsilon})^{-1/\epsilon} + (\delta_{s})^{-1/\epsilon}}{[(\delta_{s})^{-1/\epsilon} + (v_{s+1}R_{s}^{1-\epsilon})^{-1/\epsilon}]^{1-\epsilon}} \\ &= \delta_{s}v_{s+1}R_{s}^{1-\epsilon}[(\delta_{s})^{-1/\epsilon} + (v_{s+1}R_{s}^{1-\epsilon})^{-1/\epsilon}]^{\epsilon} \end{split}$$

This confirms the induction hypothesis for the CES case.

 Again, the relevant constants are found by working backwards.

## Histories and Strategies

For each time t = s, s + 1, ..., Tbetween the start s and the horizon T, let  $h^t$  denote a known history  $(w_\tau, c_\tau, \tilde{r}_\tau)_{\tau=s}^t$ of the triples  $(w_\tau, c_\tau, \tilde{r}_\tau)$ at successive times  $\tau = s, s + 1, ..., t$  up to time t.

A general policy the consumer can choose involves a measurable function  $h^t \mapsto \psi_t(h^t)$ mapping each known history up to time t, which determines the consumer's information set, into a consumption level at that time.

The collection of successive functions  $\psi_s^T = \langle \psi_t \rangle_{t=s}^T$  is what a game theorist would call the consumer's strategy in the extensive form game "against nature".

# Markov Strategies

We found an optimal solution for the two-period problem when t = T - 1.

It took the form of a Markov strategy  $\psi_t(h^t) := c_t^*(w_t)$ , which depends only on  $w_t$  as the particular state variable.

The following analysis will demonstrate in particular that at each time t = s, s + 1, ..., T, under the induction hypothesis that the consumer will follow a Markov strategy in periods  $\tau = t + 1, t + 2, ..., T$ , there exists a Markov strategy that is optimal in period t.

It will follow by backward induction that there exists an optimal strategy  $h^t \mapsto \psi_t(h^t)$ for every period  $t = s, s + 1, \dots, T$ that takes the Markov form  $h^t \mapsto w_t \mapsto c_t^*(w_t)$ .

This treats history as irrelevant, except insofar as it determines current wealth  $w_t$  at the time when  $c_t$  has to be chosen.

# A Stochastic Difference Equation

Accordingly, suppose that the consumer pursues a Markov strategy taking the form  $w_t \mapsto c_t^*(w_t)$ .

Then the Markov state variable  $w_t$  will evolve over time according to the stochastic difference equation

$$w_{t+1} = \phi_t(w_t, \tilde{r}_t) := \tilde{r}_t(w_t - c_t^*(w_t)).$$

Starting at any time t, conditional on initial wealth  $w_t$ , this equation will have a random solution  $\tilde{\mathbf{w}}_{t+1}^T = (\tilde{w}_{\tau})_{\tau=t+1}^T$ described by a unique joint conditional cdf  $F_{t+1}^T(\mathbf{w}_{t+1}^T|w_t)$ on  $\mathbb{R}^{T-s}$ .

Combined with the Markov strategy  $w_t \mapsto c_t^*(w_t)$ , this generates a random consumption stream  $\tilde{\mathbf{c}}_{t+1}^T = (\tilde{c}_{\tau})_{\tau=t+1}^T$ described by a unique joint conditional cdf  $G_{t+1}^T(\mathbf{c}_{t+1}^T|w_t)$  on  $\mathbb{R}^{T-s}$ .

Preferences and Constraints The Two Period Problem The *T* Period Problem A General Savings Problem

#### **General Problems**

#### Finite Horizon Case

Infinite Time Horizon Stationarity and the Bellman Equation Finding a Fixed Function Successive Approximation and Policy Improvement

#### Unboundedness

## General Finite Horizon Problem

Consider the objective of choosing the sequence  $(y_s, y_{s+1}, \ldots, y_{T-2}, y_{T-1})$  of controls in order to maximize

$$\mathbb{E}_{s}\left[\sum_{t=s}^{T-1}u_{s}(x_{s},y_{s})+\phi_{T}(x_{T})\right]$$

subject to the law of motion  $x_{t+1} = \xi_t(x_t, y_t, \epsilon_t)$ , where the random shocks  $\epsilon_t$ at different times  $t = s, s + 1, s + 2, \dots, T - 1$ are conditionally independent given  $x_t, y_t$ .

Here  $x_T \mapsto \phi_T(x_T)$  is the terminal state valuation function.

The stochastic law of motion can also be expressed through successive conditional probabilities  $\mathbb{P}_{t+1}(x_{t+1}|x_t, y_t)$ .

The choices of  $y_t$  at successive times determine a controlled Markov process governing the stochastic transition from each state  $x_t$  to its immediate successor  $x_{t+1}$ .

## Backward Recurrence Relation

To find the optimal solution, solve the backward recurrence relation

$$\begin{cases} V_{s}(x_{s}) &= \\ y_{s}^{*}(x_{s}) &= \arg \end{cases} \\ \max_{y_{s} \in F_{s}(x_{s})} \{ u_{s}(x_{s}, y_{s}) + \mathbb{E}_{s} [V_{s+1}(x_{s+1})|x_{s}, y_{s}] \} \end{cases}$$

where, for each start time s,

- 1.  $x_s$  denotes the "inherited state" at time s;
- 2.  $V_s(x_s)$  is the current value in state  $x_s$ of the state value function  $X \ni x \mapsto V_s(x) \in \mathbb{R}$ ;
- 3.  $X \ni x \mapsto F_s(x) \subset Y$  is the feasible set correspondence, with graph  $G_s := \{(x, y) \in X \times Y \mid y \in F_s(x)\};$
- 4.  $G_s \ni (x,y) \mapsto u_s(x,y)$  denotes the immediate return function;
- 5.  $X \ni x \mapsto y_s^*(x) \in F_s(x_s)$  is the optimal "strategy" or policy function;
- 6. The relevant terminal condition is that  $V_T(x_T)$  is given by the exogenously specified function  $\phi_T(x_T)$ .

#### Finite Horizon Case

#### Infinite Time Horizon

Stationarity and the Bellman Equation Finding a Fixed Function Successive Approximation and Policy Improvement

#### Unboundedness

# An Infinite Horizon Savings Problem

Game theorists speak of the "one-shot" deviation principle. This states that if any deviation from a particular policy or strategy improves a player's payoff, then there exists a one-shot deviation that improves the payoff.

We consider the infinite horizon extension of the consumption/investment problem already considered. Given the initial time s and initial wealth  $w_s$ , this takes the form of choosing a consumption policy  $c_t(w_t)$ at the infinite sequence t = s, s + 1, s + 2, ... of times, in order to maximize the discounted sum of total utility, given by

$$\sum_{t=s}^{\infty}\beta^{t-s}u(c_t)$$

subject to the accumulation equation  $w_{t+1} = \tilde{r}_t(w_t - c_t)$ as well as the inequality constraint  $w_t \ge 0$  for t = s + 1, s + 2, ...

## Some Assumptions

The parameter  $\beta \in (0, 1)$  is the constant discount factor. Note that utility function  $\mathbb{R} \ni c \mapsto u(c)$  is independent of t; its first two derivatives are assumed to satisfy the inequalities u'(c) > 0 and u''(c) < 0 for all  $c \in \mathbb{R}_+$ .

The investment returns  $\tilde{r}_t$  in successive periods are assumed to be i.i.d. random variables.

It is assumed that  $w_t$  in each period t is known at time t, but not before.

# Terminal Constraint

There has to be an additional constraint that imposes a lower bound on wealth at some time t.

Otherwise there would be no optimal policy — the consumer can always gain by increasing debt (negative wealth), no matter how large existing debt may be.

In the finite horizon,

there was a constraint  $w_T \ge 0$  on terminal wealth.

But here T is effectively infinite.

One might try an alternative like

$$\liminf_{t\to\infty}\beta^t w_t \ge 0$$

But this places no limit on wealth at any finite time.

We use the alternative constraint requiring that  $w_t \ge 0$  for all time.

Finite Horizon Case

### Stationarity and the Bellman Equation

Finding a Fixed Function Successive Approximation and Policy Improvement

#### Unboundedness

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

# The Stationary Problem

Our modified problem can be written in the following form that is independent of *s*:

$$\max_{c_0,c_1,\ldots,c_t,\ldots}\sum_{t=0}^{\infty}\beta^t u(c_t)$$

subject to the constraints  $0 \le c_t \le w_t$  and  $w_{t+1} = \tilde{r}_t(w_t - c_t)$  for all t = 0, 1, 2, ..., with  $w_0 = w$ , where w is given.

Because the starting time s is irrelevant, this is a stationary problem.

Define the state valuation function  $w \mapsto V(w)$ as the maximum value of the objective, as a function of initial wealth w.

It is independent of *s* because the problem is stationary.

# Bellman's Equation

For the finite horizon problem, the principle of optimality was

$$\begin{cases} V_s(w_s) &= \\ c_s^*(w_s) &= \\ \end{cases} \begin{cases} \max_{0 \le c_s \le w_s} \{ u_s(c_s) + \mathbb{E}_s[V_{s+1}(\tilde{r}_s(w_s - c_s))] \} \end{cases}$$

For the stationary infinite horizon problem, however, the time starting time s is irrelevant.

So the principle of optimality can be expressed as

$$\begin{array}{ll} V(w) & = \\ c^*(w) & = \end{array} \right\} \max_{0 \leq c \leq w} \left\{ u(c) + \beta \mathbb{E}[V(\tilde{r}(w-c))] \right\} \end{array}$$

The state valuation function  $w \mapsto V(w)$  appears on both left and right hand sides of this equation. Solving it therefore involves finding a fixed point, or function, in an appropriate function space.

# Isoelastic Case

We consider yet again the isoelastic case with a CES (or logarithmic) utility function that satisfies  $u'(c; \epsilon) \equiv c^{-\epsilon}$  and, specifically

$$u(c;\epsilon) = egin{cases} c^{1-\epsilon}/(1-\epsilon) & ext{if } \epsilon 
eq 1; \ \ln c & ext{if } \epsilon = 1. \end{cases}$$

Recall the corresponding finite horizon case,

where we found that the solution to the corresponding equations

$$\begin{array}{lll} V_s(w_s) & = \\ c_s^*(w_s) & = \end{array} \end{array} \right\} \max_{0 \leq c_s \leq w_s} \left\{ u_s(c_s) + \beta \mathbb{E}_s[V_{s+1}(\tilde{r}_s(w_s - c_s))] \right\} \end{array}$$

takes the form: (i)  $V_s(w) = \alpha_s + v_s u(w; \epsilon)$ for suitable real constants  $\alpha_s$  and  $v_s > 0$ , where  $\alpha_s = 0$  if  $\epsilon \neq 1$ ; (ii)  $c_s^*(w_s) = \gamma_s w_s$  for a suitable constant  $\gamma_s \in (0, 1)$ .

## First-Order Condition

Accordingly, we look for a solution to the stationary problem

$$\begin{array}{ll} V(w) & = \\ c^*(w) & = \end{array} \Big\} \max_{0 \leq c \leq w} \left\{ u(c; \epsilon) + \beta \mathbb{E}[V(\tilde{r}(w-c))] \right\} \end{array}$$

taking the isoelastic form  $V(w) = \alpha + vu(w; \epsilon)$ for suitable real constants  $\alpha$  and v > 0, where  $\alpha = 0$  if  $\epsilon \neq 1$ .

The first-order condition for solving this concave maximization problem is

$$c^{-\epsilon} = \beta \mathbb{E}[\tilde{r}(\tilde{r}(w-c))^{-\epsilon}] = \zeta^{\epsilon}(w-c)^{-\epsilon}$$

where  $\zeta^{\epsilon} := \beta R^{1-\epsilon}$  with R as the certainty equivalent return defined by  $R^{1-\epsilon} := \mathbb{E}[\tilde{r}^{1-\epsilon}].$ 

Hence  $c = \gamma w$  where  $\gamma^{-\epsilon} = \zeta^{\epsilon} (1 - \gamma)^{-\epsilon}$ , implying that  $\zeta = (1 - \gamma)/\gamma$ , the savings–consumption ratio. Then  $\gamma = 1/(1 + \zeta)$ , so  $1 - \gamma = \zeta/(1 + \zeta)$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

## Solution in the Logarithmic Case

When 
$$\epsilon = 1$$
 and so  $u(c; \epsilon) = \ln c$ , one has

$$V(w) = u(\gamma w; \epsilon) + \beta \{ \alpha + v \mathbb{E}[u(\tilde{r}(1 - \gamma)w; \epsilon)] \}$$
  
= ln(\gamma w) + \beta \{\alpha + v \mathbb{E}[ln(\tilde{r}(1 - \gamma)w)] \}  
= ln \gamma + (1 + \beta v) ln w + \beta \{\alpha + v \ln(1 - \gamma) + \mathbb{E}[ln \tilde{r}] \}

This is consistent with  $V(w) = \alpha + v \ln w$  in case:

- 1.  $v = 1 + \beta v$ , implying that  $v = (1 \beta)^{-1}$ ;
- 2. and also  $\alpha = \ln \gamma + \beta \{ \alpha + \nu \ln(1 \gamma) + \mathbb{E}[\ln \tilde{r}] \}$ , which implies that

$$\alpha = (1 - \beta)^{-1} \left[ \ln \gamma + \beta \left\{ (1 - \beta)^{-1} \ln(1 - \gamma) + \mathbb{E}[\ln \tilde{r}] \right\} \right]$$

This confirms the solution for the logarithmic case.

## Solution in the CES Case

When 
$$\epsilon \neq 1$$
 and so  $u(c; \epsilon) = c^{1-\epsilon}/(1-\epsilon)$ , the equation

$$V(w) = u(\gamma w; \epsilon) + \beta v \mathbb{E}[u(\tilde{r}(1-\gamma)w; \epsilon)]$$

implies that

$$(1-\epsilon)V(w) = (\gamma w)^{1-\epsilon} + \beta v \mathbb{E}[(\tilde{r}(1-\gamma)w)^{1-\epsilon}] = vw^{1-\epsilon}$$

Hence  $v = \gamma^{1-\epsilon} + \beta v (1-\gamma)^{1-\epsilon} R^{1-\epsilon}$ , so with  $\zeta^{\epsilon} = \beta R^{1-\epsilon}$  one has

$$\nu = \frac{\gamma^{1-\epsilon}}{1-\beta(1-\gamma)^{1-\epsilon}R^{1-\epsilon}} = \frac{\gamma^{1-\epsilon}}{1-(1-\gamma)^{1-\epsilon}\zeta^{\epsilon}}$$

But optimality requires  $\gamma = 1/(1+\zeta)$ , implying finally that

$$u = rac{(1+\zeta)^{\epsilon-1}}{1-\zeta(1+\zeta)^{\epsilon-1}} = rac{1}{(1+\zeta)^{1-\epsilon}-\zeta}$$

#### This confirms the solution for the CES case.

## Uniformly Bounded Returns

Suppose that the stochastic transition from each state x to the immediately succeeding state  $\tilde{x}$  is specified by a conditional probability measure  $B \mapsto \mathbb{P}(\tilde{x} \in B | x, u)$  on a  $\sigma$ -algebra of the state space.

Consider the stationary problem of choosing a policy  $x \mapsto u^*(x)$ in order to maximize the infinite discounted sum of utility

$$\mathbb{E}\sum_{t=1}^{\infty}\beta^{t-1}f(x_t,u_t)$$

where  $0 < \beta < 1$ , with  $x_1$  given and subject to  $u_t \in U(x_t)$  for t = 1, 2, ...

The return function  $(x, u) \mapsto f(x, u) \in \mathbb{R}$  is uniformly bounded provided there exist a uniform bound  $M_*$ and a uniform upper bound  $M^*$  such that

 $M_* \leq f(x,u) \leq M^*$  for all (x,u) with  $u \in U(x)$ 

### Bounds on Discounted Total Returns

The boundedness assumption  $M_* \leq f(x, u) \leq M^*$  for all (x, u)ensures that for all  $T \in \mathbb{N}$ , the finite sum

$$W_{\mathcal{T}} := \mathbb{E} \sum_{t=1}^{T} \beta^{t-1} f(x_t, u_t)$$

satisfies  $\underline{W}_{\mathcal{T}} \leq W_{\mathcal{T}} \leq \bar{W}_{\mathcal{T}}$  where

$$\underline{W}_{\mathcal{T}} := \sum_{t=1}^{T} \beta^{t-1} M_* = \frac{1-\beta^T}{1-\beta} M_*$$
$$\bar{W}_{\mathcal{T}} := \sum_{t=1}^{T} \beta^{t-1} M^* = \frac{1-\beta^T}{1-\beta} M^*$$

Then, because  $0 < \beta < 1$  and so  $\sum_{t=1}^{\infty} \beta^{t-1} = \frac{1}{1-\beta}$ , the infinite discounted sum of utility

$$W := \mathbb{E} \sum_{t=1}^{\infty} \beta^{t-1} f(x_t, u_t)$$

satisfies  $(1 - \beta) W \in [M_*, M^*]$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

60 of 86

This makes it natural to consider the linear (Banach) space  $\mathcal{V}$  of all bounded functions  $X \ni x \mapsto V(x) \in \mathbb{R}$  equipped with its sup norm defined by  $||V|| := \sup_{x \in X} |V(x)|$ . We will pay special attention to the subset

$$\mathcal{V}_M := \{ V \in \mathcal{V} \mid x \in X \Longrightarrow (1 - \beta) V(x) \in [M_*, M^*] \}$$

of state valuation functions whose values V(x) all lie within the range of the possible values of W.

# Existence and Uniqueness

Theorem

Consider the Bellman equation system

$$\begin{array}{ll} V(x) & = \\ u^*(x) & \in \end{array} \right\} \max_{u \in F(x)} \left\{ f(x, u) + \beta \mathbb{E} \left[ V(\tilde{x}) | x, u \right] \right\} \end{array}$$

Under the assumption of uniformly bounded returns satisfying  $M_* \leq f(x, u) \leq M^*$  for all (x, u):

1. among the set  $\mathcal{V}_M$ 

of state valuation functions  $X \ni x \mapsto V(x) \in \mathbb{R}$ , that satisfy the inequalities  $M_* \leq (1 - \beta)V(x) \leq M^*$  for all x, there is a unique state valuation function  $x \mapsto V(x)$ that satisfies the Bellman equation system.

 any associated policy solution X ∋ x → u\*(x) ∈ U(x) determines an optimal policy that is stationary — i.e., independent of time.

## **Two Functionals**

Given any measurable policy function  $X \ni x \mapsto u(x) \in U$ denoted by **u**, define the mapping  $\mathcal{V}_M \ni V \mapsto T^{\mathbf{u}}V \in \mathcal{V}$ so that for all  $x \in X$  one has

 $[T^{\mathbf{u}}V](x) := f(x, u(x)) + \beta \mathbb{E}\left[V(\tilde{x})|x, u(x)\right]$ 

When the state is x, this gives the value  $[T^{\mathbf{u}}V](x)$ of choosing the policy u(x) for one period, and then experiencing a future discounted return  $V(\tilde{x})$ after reaching each possible subsequent state  $\tilde{x} \in X$ .

Define also the mapping  $\mathcal{V}_M \ni V \mapsto T^*V \in \mathcal{V}$ so that for all  $x \in X$  one has

$$[T^*V](x) := \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E} \left[V(\tilde{x})|x, u\right]\}$$

### Compressed Bellman Equation

The Bellman equation system is

$$\begin{array}{ll} V(x) & = \\ u^*(x) & \in \end{array} \right\} \max_{u \in F(x)} \left\{ f(x,u) + \beta \mathbb{E} \left[ V(\tilde{x}) | x, u \right] \right\} \end{array}$$

We have defined the two functionals that map  $\mathcal{V}_M$  into  $\mathcal{V}$ so that, for all  $x \in X$ , one has

$$[T^{\mathbf{u}}V](x) := f(x, u(x)) + \beta \mathbb{E}[V(\tilde{x})|x, u(x)]$$
  
$$[T^{*}V](x) := \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E}[V(\tilde{x})|x, u]\}$$

The definitions of these two functionals allow the Bellman equation system to be rewritten as

$$V(x) = [T^*V](x)$$
  
$$u^*(x) \in \arg \max_{u \in F(x)} [T^uV](x)$$

In particular, the state valuation function  $X \ni x \mapsto V(x)$ should be a fixed point of  $T^*$  in the space  $\mathcal{V}_M$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

## Two Mappings of $\mathcal{V}_M$ into Itself

For all  $V \in \mathcal{V}_M$ , policies **u**, and  $x \in X$ , we have defined

$$[T^{\mathbf{u}}V](x) := f(x, u(x)) + \beta \mathbb{E}[V(\tilde{x})|x, u(x)]$$
  
and 
$$[T^{*}V](x) := \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E}[V(\tilde{x})|x, u]\}$$

Recall the uniform boundedness condition  $M_* \leq f(x, u) \leq M^*$ , together with the assumption that V belongs to the domain  $\mathcal{V}_M$  of functions satisfying  $M_* \leq (1 - \beta)V(\tilde{x}) \leq M^*$  for all  $\tilde{x}$ .

So these two definitions jointly imply that, for all  $x \in X$ , one has

$$[T^{\mathbf{u}}V](x) \geq M_* + \beta (1-\beta)^{-1} M_* = (1-\beta)^{-1} M_*$$
  
and  $[T^{\mathbf{u}}V](x) \leq M^* + \beta (1-\beta)^{-1} M^* = (1-\beta)^{-1} M^*$ 

Similarly, given any  $V \in \mathcal{V}_M$ , for all  $x \in X$ one has  $M_* \leq (1 - \beta) [T^*V](x) \leq M^*$  for all  $x \in X$ .

Therefore both functionals  $V \mapsto T^{\mathbf{u}}V$  and  $V \mapsto T^*V$ map the set  $\mathcal{V}_M$  of bounded functions into itself.

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

# A First Contraction Mapping

The definition  $[T^{\mathbf{u}}V](x) := f(x, u(x)) + \beta \mathbb{E}[V(\tilde{x})|x, u(x)]$ implies that for any two functions  $V_1, V_2 \in \mathcal{V}_M$ , one has

$$[T^{\mathbf{u}}V_1](x) - [T^{\mathbf{u}}V_2](x) = \beta \mathbb{E} \left[ V_1(\tilde{x}) - V_2(\tilde{x}) | x, u(x) \right]$$

The definition of the sup norm therefore implies that

$$\begin{aligned} \|T^{\mathbf{u}}V_{1} - T^{\mathbf{u}}V_{2}\| &= \sup_{x \in X} |[T^{\mathbf{u}}V_{1}](x) - [T^{\mathbf{u}}V_{2}](x)| \\ &= \sup_{x \in X} |\beta \mathbb{E} [V_{1}(\tilde{x}) - V_{2}(\tilde{x})|x, u(x)]| \\ &= \beta \sup_{x \in X} |\mathbb{E} [V_{1}(\tilde{x}) - V_{2}(\tilde{x})|x, u(x)]| \\ &\leq \beta \sup_{\tilde{x} \in X} |V_{1}(\tilde{x}) - V_{2}(\tilde{x})| \\ &= \beta \|V_{1} - V_{2}\| \end{aligned}$$

Hence  $\mathcal{V}_M \ni V \mapsto T^{\mathbf{u}}V \in \mathcal{V}_M$ is a contraction mapping with factor  $\beta < 1$ . Applying the Contraction Mapping Theorem, I

For each fixed policy  $\boldsymbol{u},$  the contraction mapping

$$\mathcal{V}_M \ni V \mapsto T^{\mathbf{u}} V \in \mathcal{V}_M$$

has a unique fixed point in the form of a function  $V^{\mathbf{u}} \in \mathcal{V}_M$ .

Furthermore, given any initial function  $V \in \mathcal{V}_M$ , consider the infinite sequence of mappings  $[T^{\mathbf{u}}]^k V$   $(k \in \mathbb{N})$  that result from applying the operator  $T^{\mathbf{u}}$  iteratively k times.

The contraction mapping property of  $T^{\mathbf{u}}$ implies that  $\|[T^{\mathbf{u}}]^k V - V^{\mathbf{u}}\| \to 0$  as  $k \to \infty$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

### Characterizing the Fixed Point, I

Starting from  $V_0 = 0$  and given any initial state  $x \in X$ , note that

$$\begin{bmatrix} T^{\mathbf{u}} \end{bmatrix}^k V_0(x) = \begin{bmatrix} T^{\mathbf{u}} \end{bmatrix} \left( \begin{bmatrix} T^{\mathbf{u}} \end{bmatrix}^{k-1} V_0 \right)(x) \\ = f(x, u(x)) + \beta \mathbb{E} \left[ \left( \begin{bmatrix} T^{\mathbf{u}} \end{bmatrix}^{k-1} V_0 \right)(\tilde{x}) | x, u(x) \right]$$

It follows by induction on k that  $[T^{\mathbf{u}}]^k V_0(\bar{x})$  equals the expected discounted total payoff  $\mathbb{E} \sum_{t=1}^k \beta^{t-1} f(x_t, u_t)$  of starting from  $x_0 = \bar{x}$ 

and then following the policy  $x \mapsto u(x)$  for k subsequent periods.

Taking the limit as  $k \to \infty$ , it follows that for any state  $\bar{x} \in X$ , the value  $V^{\mathbf{u}}(\bar{x})$  of the fixed point in  $\mathcal{V}_M$  is the expected discounted total payoff

$$\mathbb{E}\sum_{t=1}^{\infty}\beta^{t-1}f(x_t,u_t)$$

68 of 86

of starting from  $x_0 = \bar{x}$ and then following the policy  $x \mapsto u(x)$  for ever thereafter. University of Warwick, EC9A0 Maths for Economists, Day 10 Peter J. Hammond

## A Second Contraction Mapping

For each state  $x \in X$ , recall the definition

$$[T^*V](x) := \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E} \left[V(\tilde{x})|x, u\right]\}$$

Given any state  $x \in X$  and any two functions  $V_1, V_2 \in \mathcal{V}_M$ , define  $u_1, u_2 \in F(x)$  so that for k = 1, 2 one has

$$[T^*V_k](x) = f(x, u_k) + \beta \mathbb{E} [V_k(\tilde{x})|x, u_k] \}$$

Note that  $[T^*V_2](x) \ge f(x, u_1) + \beta \mathbb{E} [V_2(\tilde{x})|x, u_1]$  implying that

$$\begin{array}{rcl} [T^*V_1](x) - [T^*V_2](x) &\leq & \beta \mathbb{E} \left[ V_1(\tilde{x}) - V_2(\tilde{x}) | x, u_1 \right] \\ &\leq & \beta \| V_1 - V_2 \| \end{array}$$

Similarly, interchanging 1 and 2 in the above argument gives  $[T^*V_2](x) - [T^*V_1](x) \le \beta ||V_1 - V_2||$ . Hence  $||T^*V_1 - T^*V_2|| \le \beta ||V_1 - V_2||$ , so  $T^*$  is also a contraction.

# Applying the Contraction Mapping Theorem, II

Similarly the contraction mapping  $V \mapsto T^*V$ has a unique fixed point in the form of a function  $V^* \in \mathcal{V}_M$ such that  $V^*(\bar{x})$  is the maximized expected discounted total payoff of starting in state  $x_0 = \bar{x}$ and following an optimal policy for ever thereafter.

Moreover, 
$$V^* = T^* V^* = T^{u^*} V^*$$
.

This implies that  $V^*$  is also the value of following the policy  $x \mapsto u^*(x)$  throughout, which must therefore be an optimal policy.

## Characterizing the Fixed Point, II

Starting from  $V_0 = 0$  and given any initial state  $x \in X$ , note that

$$\begin{aligned} [T^*]^k V_0(x) &= [T^*] \left( [T^*]^{k-1} V_0 \right)(x) \\ &= \max_{u \in F(x)} \{ f(x, u) + \beta \mathbb{E} \left[ \left( [T^*]^{k-1} V_0 \right)(\tilde{x}) | x, u \right] \} \end{aligned}$$

It follows by induction on kthat  $[T^*]^k V_0(\bar{x})$  equals the maximum possible expected discounted total payoff  $\mathbb{E} \sum_{t=1}^k \beta^{t-1} f(x_t, u_t)$ of starting from  $x_1 = \bar{x}$ and then following the "backward" sequence of optimal policies  $(u_k^*, u_{k-1}^*, u_{k-2}^*, \dots, u_2^*, u_1^*)$ , where for each k the policy  $x \mapsto u_k^*(x)$ is optimal when k periods remain.

# Outline

### Stochastic Linear Difference Equations in One Variable Explicit Solution Gaussian Disturbances

#### **Optimal Saving**

Preferences and Constraints The Two Period Problem The *T* Period Problem A General Savings Problem

#### **General Problems**

Finite Horizon Case Infinite Time Horizon Stationarity and the Bellman Equation Finding a Fixed Function

Successive Approximation and Policy Improvement

#### Unboundedness

# Method of Successive Approximation

The method of successive approximation starts with an arbitrary function  $V_0 \in \mathcal{V}_M$ .

For k = 1, 2, ..., it then repeatedly solves the pair of equations  $V_k = T^* V_{k-1} = T^{u_k^*} V_{k-1}$ to construct sequences of:

- 1. state valuation functions  $X \ni x \mapsto V_k(x) \in \mathbb{R}$ ;
- policies X ∋ x ↦ u\_k^\*(x) ∈ F(x) that are optimal given that one applies the preceding state valuation function X ∋ x̃ ↦ V<sub>k-1</sub>(x̃) ∈ ℝ to each immediately succeeding state x̃.

Because the operator  $V \mapsto T^*V$  on  $\mathcal{V}_M$  is a contraction mapping, the method produces

a convergent sequence  $(V_k)_{k=1}^{\infty}$  of state valuation functions whose limit satisfies  $V^* = T^*V^* = T^{u^*}V^*$ for a suitable policy  $X \ni x \mapsto u^*(x) \in F(x)$ .

## Monotonicity

For all functions  $V \in \mathcal{V}_M$ , policies **u** defined as a function  $X \ni x \mapsto u(x) \in F(x)$ , and states  $x \in X$ , we have defined  $[T^{\mathbf{u}}V](x) := f(x, u(x)) + \beta \mathbb{E}[V(\tilde{x})|x, u(x)]$ and  $[T^*V](x) := \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E}[V(\tilde{x})|x, u]\}$ 

### Notation

Given any pair  $V_1, V_2 \in \mathcal{V}_M$ , we write  $V_1 \ge V_2$ to indicate that the inequality  $V_1(x) \ge V_2(x)$  holds for all  $x \in X$ .

### Definition

An operator  $\mathcal{V}_M \ni V \mapsto TV \in \mathcal{V}_M$  is monotone just in case whenever  $V_1, V_2 \in \mathcal{V}_M$  satisfy  $V_1 \geqq V_2$ , one has  $TV_1 \geqq TV_2$ .

### Theorem

The following operators on  $\mathcal{V}_M$  are monotone:

- 1.  $V \mapsto T^{\mathbf{u}}V$  for all policies  $\mathbf{u}$ ;
- 2.  $V \mapsto T^*V$  for the optimal policy.

#### The proofs will occupy the next two slides.

University of Warwick, EC9A0 Maths for Economists, Day 10

### Proof that the Operator $T^{u}$ is Monotone

Given any state  $x \in X$  and any two functions  $V_1, V_2 \in \mathcal{V}_M$ , the definition of  $\mathcal{T}^u$  implies that

$$[T^{\mathbf{u}}V_1](x) := f(x, u(x)) + \beta \mathbb{E} [V_1(\tilde{x})|x, u(x)]$$
  
and 
$$[T^{\mathbf{u}}V_2](x) := f(x, u(x)) + \beta \mathbb{E} [V_2(\tilde{x})|x, u(x)]$$

Subtracting the second equation from the first implies that

$$[T^{\mathbf{u}}V_1](x) - [T^{\mathbf{u}}V_2](x) = \beta \mathbb{E} \left[V_1(\tilde{x}) - V_2(\tilde{x})|x, u(x)\right]$$

If  $V_1 \ge V_2$  and so the inequality  $V_1(\tilde{x}) \ge V_2(\tilde{x})$  holds for all  $\tilde{x} \in X$ , it follows that  $[T^{\mathbf{u}}V_1](x) \ge [T^{\mathbf{u}}V_2](x)$ .

Since this holds for all  $x \in X$ , we have proved that  $T^{\mathbf{u}}V_1 \geqq T^{\mathbf{u}}V_2$ .

### Proof that the Operator $T^*$ is Monotone

Given any state  $x \in X$  and any two functions  $V_1, V_2 \in \mathcal{V}_M$ , define  $u_1, u_2 \in F(x)$  so that for k = 1, 2 one has

$$[T^*V_k](x) = \max_{u \in F(x)} \{f(x, u) + \beta \mathbb{E} [V_k(\tilde{x})|x, u]\}$$
  
= 
$$[T^{\mathbf{u}_k}V_k](x) = f(x, u_k) + \beta \mathbb{E} [V_k(\tilde{x})|x, u_k]$$

Because  $u_2$  may be suboptimal given  $V_1$ , it follows that

$$[T^*V_1](x) \ge f(x, u_2) + \beta \mathbb{E}[V_1(\tilde{x})|x, u_2]$$
  
whereas  $[T^*V_2](x) = f(x, u_2) + \beta \mathbb{E}[V_2(\tilde{x})|x, u_2]$ 

Subtracting the second equation from the first inequality gives

$$[T^*V_1](x) - [T^*V_2](x) \ge \beta \mathbb{E} [V_1(\tilde{x}) - V_2(\tilde{x})|x, u_2]$$

If  $V_1 \ge V_2$  and so the inequality  $V_1(\tilde{x}) \ge V_2(\tilde{x})$  holds for all  $\tilde{x} \in X$ , it follows that  $[T^*V_1](x) \ge [T^*V_2](x)$ .

Since this inequality holds for all  $x \in X$ , we have proved that  $T^*V_1 \ge T^*V_2$ . University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

76 of 86

# The Method of Policy Improvement

The method of policy improvement starts with any fixed policy  $\mathbf{u}_0$  or  $X \ni x \mapsto u_0(x) \in F(x)$ , along with the value  $V^{\mathbf{u}_0} \in \mathcal{V}_M$  of following that policy for ever.

Note that, among the domain  $\mathcal{V}_M$  of suitably bounded functions, the value  $V^{\mathbf{u}_0}$  is the unique fixed point satisfying  $V^{\mathbf{u}_0} = \mathcal{T}^{\mathbf{u}_0} V^{\mathbf{u}_0}$ .

At each step k = 1, 2, ..., given the previous policy  $\mathbf{u}_{k-1}$ and associated value  $V^{\mathbf{u}_{k-1}}$  satisfying  $V^{\mathbf{u}_{k-1}} = T^{\mathbf{u}_{k-1}}V^{\mathbf{u}_{k-1}}$ , choose:

- 1. the policy  $\mathbf{u}_k$  or  $X \ni x \mapsto u_k(x) \in F(x)$  optimally, so that  $T^*V^{\mathbf{u}_{k-1}} = T^{\mathbf{u}_k}V^{\mathbf{u}_{k-1}}$ ;
- the state valuation function x → V<sub>k</sub>(x) as the unique fixed point in V<sub>M</sub> of the operator T<sup>uk</sup>.

# Policy Improvement Theorem

#### Theorem

The infinite sequence  $(\mathbf{u}_k, V^{\mathbf{u}_k})_{k \in \mathbb{N}}$ consisting of pairs of policies  $\mathbf{u}_k$ with their associated valuation functions  $V^{\mathbf{u}_k} \in \mathcal{V}_M$  satisfies

1. 
$$V^{\mathbf{u}_k} \geq V^{\mathbf{u}_{k-1}}$$
 for all  $k \in \mathbb{N}$  (policy improvement);

2. 
$$\|V^{\mathbf{u}_k} - V^*\| \to 0$$
 as  $k \to \infty$ ,  
where  $V^*$  is the infinite-horizon optimal  
state valuation function in  $\mathcal{V}_M$  that satisfies  $T^*V^* = V^*$ .

The proof will occupy the next three slides.

University of Warwick, EC9A0 Maths for Economists, Day 10

### Proof of Policy Improvement

By definition of the optimality operator  $T^*$ , one has  $T^*V \ge T^{\mathbf{u}}V$  for all functions  $V \in \mathcal{V}_M$  and all policies  $\mathbf{u}$ .

So at each step k of the policy improvement routine, one has

$$T^{\mathbf{u}_{k}}V^{\mathbf{u}_{k-1}} = T^{*}V^{\mathbf{u}_{k-1}} \ge T^{\mathbf{u}_{k-1}}V^{\mathbf{u}_{k-1}} = V^{\mathbf{u}_{k-1}}$$

In particular,  $V^{\mathbf{u}_{k-1}} \leq T^{\mathbf{u}_k} V^{\mathbf{u}_{k-1}}$ .

Because the operator  $T^{\mathbf{u}_k}$  is monotonic, applying it iteratively implies that

$$V^{\mathbf{u}_{k-1}} \leq T^{\mathbf{u}_k} V^{\mathbf{u}_{k-1}} \leq [T^{\mathbf{u}_k}]^2 V^{\mathbf{u}_{k-1}} \leq \dots$$
$$\dots \leq [T^{\mathbf{u}_k}]^r V^{\mathbf{u}_{k-1}} \leq [T^{\mathbf{u}_k}]^{r+1} V^{\mathbf{u}_{k-1}} \leq \dots$$

But the definition of  $V^{\mathbf{u}_k}$  implies that for all  $V \in \mathcal{V}_M$ , including  $V = V^{\mathbf{u}_{k-1}}$ , one has  $\|[T^{\mathbf{u}_k}]^r V - V^{\mathbf{u}_k}\| \to 0$  as  $r \to \infty$ . Hence  $V^{\mathbf{u}_k} = \sup_r [T^{\mathbf{u}_k}]^r V^{\mathbf{u}_{k-1}} \ge V^{\mathbf{u}_{k-1}}$ , thus confirming that the policy  $\mathbf{u}_k$  does improve  $\mathbf{u}_{k-1}$ .

### Proof of Convergence, I

Recall that at each step  $k \in \mathbb{N}$  of the policy improvement routine, one has  $T^{\mathbf{u}_k}V^{\mathbf{u}_{k-1}} = T^*V^{\mathbf{u}_{k-1}}$  and also  $T^{\mathbf{u}_k}V^{\mathbf{u}_k} = V^{\mathbf{u}_k}$ . Now, for each state  $x \in X$ , define  $\hat{V}(x) := \sup_{k \in \mathbb{N}} V^{\mathbf{u}_k}(x)$ . First, because  $V^{\mathbf{u}_k} \geq V^{\mathbf{u}_{k-1}}$  and  $T^{\mathbf{u}_k}$  is monotonic, one has  $V^{\mathbf{u}_{k}} = T^{\mathbf{u}_{k}}V^{\mathbf{u}_{k}} \geq T^{\mathbf{u}_{k}}V^{\mathbf{u}_{k-1}} = T^{*}V^{\mathbf{u}_{k-1}}$ . Then, because  $V^{\mathbf{u}_k} \geq V^{\mathbf{u}_{k-1}}$  and  $T^*$  is monotonic, it follows that

$$\hat{V} = \sup_{k} V^{\mathbf{u}_{k}} \geq \sup_{k} T^{*} V^{\mathbf{u}_{k-1}} = T^{*}(\sup_{k} V^{\mathbf{u}_{k-1}}) = T^{*} \hat{V}$$

Second, the definition of  $T^*$  implies that  $V^{\mathbf{u}_k} = T^{\mathbf{u}_k} V^{\mathbf{u}_k}$ .

Similarly  $V^{\mathbf{u}_k} = T^{\mathbf{u}_k} V^{\mathbf{u}_k} \leq T^* V^{\mathbf{u}_k}$  for each  $k \in \mathbb{N}$ .

Because  $T^*$  is monotonic, it follows that

$$\hat{V} = \sup_{k} V^{\mathbf{u}_{k}} = \sup_{k} T^{\mathbf{u}_{k}} V^{\mathbf{u}_{k}} \leq \sup_{k} T^{*} V^{\mathbf{u}_{k}} = T^{*}(\sup_{k} V^{\mathbf{u}_{k}}) = T^{*} \hat{V}$$

So we have proved that  $\hat{V} \geq T^* \hat{V}$  and that  $\hat{V} \leq T^* \hat{V}$ , which together imply that  $\hat{V} = T^* \hat{V}$ . Peter J. Hammond University of Warwick, EC9A0 Maths for Economists, Day 10

# Proof of Convergence, II

We have proved that  $\hat{V} = T^* \hat{V}$  where  $\hat{V} = \sup_k V^{\mathbf{u}_k}$ . But earlier we defined  $V^*$  as the unique fixed point of the contraction mapping  $T^*$ , satisfying  $V^* = T^* V^* = T^{\mathbf{u}^*} V^*$ . It follows that  $V^* = \hat{V} = \sup_k V^{\mathbf{u}_k}$ . But by construction the sequence  $V^{\mathbf{u}_k}(x)$  is non-decreasing.

It follows that  $V^{\mathbf{u}_k}(x) \to V^*(x)$  for each  $x \in X$ .

Finite Horizon Case Infinite Time Horizon Stationarity and the Bellman Equation Finding a Fixed Function Successive Approximation and Policy Improvement

#### Unboundedness

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

## Unbounded Utility

In economics the boundedness condition  $M_* \leq f(x, u) \leq M^*$  is rarely satisfied!

Consider for example, for each parameter value  $\epsilon > 0$ , the isoelastic utility function  $\mathbb{R}_{++} \ni c \mapsto u(c; \epsilon) \in \mathbb{R}$  defined by

$$u(c;\epsilon) = egin{cases} rac{c^{1-\epsilon}}{1-\epsilon} & ext{if } \epsilon > 0 ext{ and } \epsilon 
eq 1 \ \ln c & ext{if } \epsilon = 1 \end{cases}$$

This function is obviously:

- 1. bounded below but unbounded above in case 0 <  $\epsilon$  < 1;
- 2. unbounded both above and below in case  $\epsilon = 1$ ;
- 3. bounded above but unbounded below in case  $\epsilon > 1$ .

Also commonly used is the negative exponential utility function defined by  $u(c) = -e^{-\alpha c}$ 

where  $\alpha$  is the constant absolute rate of risk aversion (CARA).

This function is bounded above and, provided that  $c \ge 0$ , also bounded below.

University of Warwick, EC9A0 Maths for Economists, Day 10

Peter J. Hammond

# Warning Example: The Optimization Problem

The following example shows that there can be irrelevant unbounded solutions to the Bellman equation.

### Example

Consider the problem of maximizing  $\sum_{t=0}^{\infty} \beta^t (1-u_t)$ 

where  $u_t \in [0, 1]$ ,  $0 < \beta < 1$ , and  $x_{t+1} = \frac{1}{\beta}(x_t + u_t)$ , with  $x_0 > 0$ .

Notice that  $x_{t+1} \ge \frac{1}{\beta} x_t$  implying that  $x_t \ge \beta^{-t} x_0 \to \infty$  as  $t \to \infty$ .

Of course the return function  $[0,1] \ni u \mapsto f(x,u) = 1 - u \in [0,1]$  is uniformly bounded.

## Warning Example: Unbounded Spurious Solution

The Bellman equation is

$$\begin{array}{rcl} J(x) & = \\ u^*(x) & = \end{array} \right\} \max_{u \in [0,1]} \left\{ 1 - u + \beta J\left(\frac{1}{\beta}(x+u)\right) \right\} \\ \end{array}$$

Even though the return function is uniformly bounded, this Bellman equation has an unbounded spurious solution.

Indeed, we find a spurious solution with  $J(x) \equiv \gamma + x$  for a suitable constant  $\gamma$ .

The condition for this to solve the Bellman equation is that

$$\begin{array}{lll} \gamma + x & = & \max_{u \in [0,1]} \left\{ 1 - u + \beta \left[ \gamma + \frac{1}{\beta} (x+u) \right] \right\} \\ & = & \max_{u \in [0,1]} \left\{ 1 + \beta \gamma + x \right\} = & 1 + \beta \gamma + x \end{array}$$

This is true if and only if  $\gamma = 1 + \beta \gamma$ , implying that  $\gamma = (1 - \beta)^{-1}$ .

University of Warwick, EC9A0 Maths for Economists, Day 10

## Warning Example: True Solution

The problem is to maximize  $\sum_{t=0}^{\infty} \beta^t (1-u_t)$ 

where  $u_t \in [0, 1]$ ,  $0 < \beta < 1$ , and  $x_{t+1} = \frac{1}{\beta}(x_t + u_t)$ , with  $x_0 > 0$ .

The obvious optimal policy is to choose  $u_t = 0$  for all t, giving the maximized value  $J(x) = \sum_{t=0}^{\infty} \beta^t = (1 - \beta)^{-1}$ .

Indeed, consider the bounded function  $J(x) = (1 - \beta)^{-1}$ , together with  $u^* = 0$ , both independent of x.

These do indeed solve the Bellman equation because

$$J(x) = \max_{u \in [0,1]} \left\{ 1 - u + \beta J \left( \frac{1}{\beta} (x+u) \right) \right\}$$
  
=  $\max_{u \in [0,1]} \left\{ 1 - u + \beta (1-\beta)^{-1} \right\}$   
=  $1 + \frac{\beta}{1-\beta} = \frac{1}{1-\beta}$
