## Abstract

This paper studies an economy where privately informed hedge funds (HFs) trade a risky asset in order to exploit potential mispricings. HFs are allowed to have access to credit, by using their risky assets as collateral. We analyse the role of the degree of heterogeneity among HFs' demand for the risky asset in the emergence of clustering of defaults. We find that fire-sales caused by margin calls is a necessary, yet not a sufficient condition for defaults to be clustered. We show that when the degree of heterogeneity is sufficiently high, poorly performing HFs are able to obtain a higher than usual market share at the end of the leverage cycle, which leads to an improvement of their performance. Consequently, their survival time is prolonged, increasing the

## 1. Introduction

The hedge fund (HF) industry has experienced an explosive growth in recent years. The total size of the assets managed by HFs in 2015 was estimated at US\$2.74 trillion ([BarclayHedge, 2016](#)). Due to the increasing weight of HFs in the financial market, failures of HFs can pose a major threat to the stability of the global financial system. The default of a number of high profile HFs, such as LTCM and HFs owned by Bear Stearns ([Haghani, 2014](#)), testifies to this.

At the same time, poor performance of HFs—the prelude to the failure of a HF—is empirically found to be strongly correlated across HFs ([Boyson et al., 2010](#)), a phenomenon known as “contagion”. Moreover, [Boyson et al. \(2010\)](#) point out that the correlation between HFs’ worst returns—falling in the bottom 10% of a HF style’s monthly returns—remains high, even after taking into account that HF returns are autocorrelated, and the effect of the exposure of HFs to commonly known risk factors. The findings of [Boyson et al. \(2010\)](#) support the theoretical predictions of [Brunnermeier and Pedersen \(2009\)](#), who provide a mechanism revealing how liquidity shocks can

lead to downward liquidity spirals and thus to contagion<sup>1</sup>. The mechanism that leads to contagion is closely related to the theory of the “leverage cycle”, i.e. the pro-cyclical increase and decrease of leverage, due to the interplay between equity volatility and leverage, put forward by [Geanakoplos \(1997\)](#)<sup>2</sup>.

The combination of the dominant role of HFs in the financial system with the possibility of transmission of the risk, not only to other financial organisations but also to the real economy, has placed the operation of HFs under close scrutiny and has highlighted the significance of regulation of the industry. Regulating the HF industry is not an easy task; designing the appropriate regulation requires a good understanding of many aspects such as the mechanism which generates defaults at the individual level, the mechanism behind contagion, and finally the parameters which determine the persistency of the effect of a default of an individual HF on the industry. Although [Brunnermeier and Pedersen \(2009\)](#) provide the mechanism behind contagion, they overlooked the persistency of the impact of a default of an individual HF. Our paper aims to fill this gap. In particular, we characterise the conditions under which the correlation between HF’s defaults is persistent, i.e. defaults are clustered.

We study an economy with heterogeneous interacting agents (HIA) –

---

<sup>1</sup>Other works which study the the causes of contagion in financial markets include [Kyle and Xiong \(2001\)](#), and [Kodres and Pritsker \(2002\)](#).

<sup>2</sup>In fact the theory of leverage cycle, in contrast to other models that endogenise leverage ([Brunnermeier and Pedersen, 2009](#); [Brunnermeier and Sannikov, 2014](#); [Vayanos and Wang, 2012](#)) has the additional merit of making the endogenous determination of collateral possible.

HFs in our case – in the tradition of [Day and Huang \(1990\)](#), [Brock and LeBaron \(1996\)](#), [Brock and Hommes \(1997, 1998\)](#), [Chiarella and He \(2002\)](#), [Thurner et al. \(2012\)](#) and [Poledna et al. \(2014\)](#) among others.<sup>3</sup> We find that the feedback between market volatility and margin requirements (downward liquidity spiral), is a necessary yet not a sufficient condition for clustering of defaults to occur, as has been suggested by [Boyson et al. \(2010\)](#). In this work we show that heterogeneity plays a pivotal role in the emergence of clustered defaults: defaults are clustered only if the degree of heterogeneity is sufficiently high.

We develop a simple dynamic model with a representative mean-reverting noise trader and a finite number of HF managers trading a risky asset. We allow for a setup where heterogeneity regarding the demand of the risky asset may be due to different preferences towards risk, disagreement on the expected price of the asset, or disagreement on the volatility of the market. Evidently, market volatility depends on the HFs' trading strategy, which in turn, depends on HFs' demand. In addition, we allow for the HFs to have access to credit, and we endogenise the probability of default by assuming that a HF would choose to default when its portfolio value falls below a threshold.

In this environment we show that when the degree of heterogeneity is sufficiently high, poorly performing HFs are able to absorb shocks caused by fire sales. As a result, they obtain a larger than usual market share, and improve their performance. In this fashion, a default due to exactly their

---

<sup>3</sup>For a detailed relevant literature review see [Hommes \(2006\)](#), [LeBaron \(2006\)](#) and [Chiarella et al. \(2009\)](#).

poor performance is delayed, allowing them to remain in operation until the downturn of the next leverage cycle. This leads to the increase of the probability of poorly and high-performing hedge funds to default in sync at a later time, and thus the probability of collective defaults. Formally, we show that for high degree of heterogeneity the default time-sequence shows infinite memory. Using the definition of [Andersen and Bollerslev \(1997\)](#) clustering is determined by the divergence of the sum (or integral in continuous time) of the autocorrelation function (ACF) of the default time sequence, and therefore, the presence of infinite memory in the underlying stochastic process describing the occurrence of defaults. Furthermore, we establish a quantitative connection between the non-trivial aggregate statistics and the presence of infinite memory in the underlying stochastic process governing the defaults of the HFs. The comparison between the theoretical prediction of the asymptotic behaviour of the autocorrelation function (ACF) of defaults and the numerical findings, reveals that our theoretical predictions are valid even in a market with a finite number of HFs and the clustering of defaults is confirmed.

The structure of the rest of the paper is as follows. Section [2](#) discusses the relevant literature. Section [3](#) presents the economic framework that we use. In section [4.1](#) discusses the numerical findings. In Section [4.2](#), we provide analytical results linking the heavy-tailed aggregate density to the observed statistical character of defaults on a microscopic level, and the power-law decay of the ACF of the default time-series of defaults, identifying that defaults are clustered. Finally, section [5](#) provides a short summary with concluding remarks.

## 2. Relevant Literature

Our paper is related methodologically to the HIA literature; and in terms of content, to the literature which studies the effects of leverage on financial stability.<sup>4</sup> Models with HIA can give rise to emergent properties of systems that are able to replicate the empirical trends seen in asset prices, asset returns and their distributions (Lux, 1995, 1998; Lux and Marchesi, 1999; Iori, 2002; He and Li, 2007; Chiarella et al., 2014). In Levy (2008), spontaneous crashes are a natural property of a market with heterogeneous investors who are inclined to conform to their peers, under the condition that the strength of the conformity effects is large compared to the degree of heterogeneity of the investors. In other papers, such as Chiarella (1992), Lux (1995) and Di Guilmi et al. (2014) heterogeneity has to do with the different beliefs and trading rules of the agents (fundamentalists and chartists) which can result to asset price fluctuations and market instability.

The set up of our model is similar to Thurner et al. (2012) and Poledna et al. (2014) which study the effects of leverage in an economy with heterogeneous HFs. Thurner et al. (2012) show that leverage causes fat tails and clustered volatility. Under benign market conditions HFs become more leveraged as this is then more profitable. High levels of leverage are correlated with increased asset price fluctuations that become heavy-tailed. The heavy tails are caused by the fact that when a HF reaches its maximum leverage

---

<sup>4</sup>The present paper focuses on the role of leverage on a microeconomic level and does not discuss the feedback effects with the Macroeconomy. For the latter see Chiarella and Di Guilmi (2011), Ryoo (2010) and references therein.

limit then it has to repay part of its loan by selling some of its assets. [Poledna et al. \(2014\)](#) use a very similar framework to test three regulatory policies: (i) imposing limits on the maximum leverage, (ii) similar to the Basle II regulations, and (iii) a hypothetical perfect hedging scheme, in which the banks hedge against the leverage-induced risk using options. They find that the effectiveness of the policies depends on the levels of leverage, and that even though the perfect hedging scheme reduces volatility in comparison to the Basle II scheme, none of these are able to make the system considerably safer on a systemic level.

Our model extends this framework in two directions. Firstly, in our model the behaviour of HFs is not given by heuristics but it is derived from first principles. In both [Thurner et al. \(2012\)](#) and [Poledna et al. \(2014\)](#), HFs are risk neutral and have different demand of the asset given the same information and the same wealth. The characteristic which makes them heterogeneous, is called “aggression” and aims to capture the different responses of the agents to a mispricing signal. Given the risk neutrality assumption, it is impossible to provide a rigorous explanation for the difference in aggression. Furthermore, deriving the HFs demand functions from first principles: (i) we bridge the gap between [Thurner et al. \(2012\)](#) and [Poledna et al. \(2014\)](#); and the rest of the leverage cycle literature discussed below and (ii) we provide a framework which allows the study of different types of heterogeneity.

The leverage cycle models start with the collateral equilibrium models of [Geanakoplos \(1997\)](#) and [Geanakoplos and Zame \(1997\)](#), who provide a general equilibrium model of collateral. The key idea behind these models is that lenders require a collateral from the borrowers in order to lend them funds.

This borrowing and lending is agreed through a contract of a promise of paying back the loan in future states, where the investor who sells the contract is borrowing money –using a collateral to back the promise– from the agent who buys the contract. Each contract is chosen from a menu of contracts with different loan to value (LTV) ratio. In [Geanakoplos \(1997\)](#) scarcity of collateral leads to only a few contracts being traded, which makes leverage (LTV) endogenous. Finally, the investors default when the the value of the collateral is less than the value of the contract that borrowers and lenders have agreed. [Geanakoplos \(2003\)](#) considers a continuum of risk neutral agents with different priors in a binomial economy with two or three states of the world. He shows how changes in volatility lead to changes in equilibrium leverage which in turn have a bigger effect in asset prices than what agents believe to be the effect of news. [Geanakoplos \(2003, 1997\)](#) show that in some cases all agents will choose the same contract from the contract menu. This result has been recently extended by [Fostel and Geanakoplos \(2015\)](#) who study in more detail the relationship between leverage and default and prove that in all binomial economies with financial assets, exactly one contract is chosen.

[Fostel and Geanakoplos \(2008\)](#) extend the economy of [Geanakoplos \(2003\)](#) to an economy with multiple assets and two risk averse agents instead of a continuum of risk neutral ones; and develop an asset pricing theory which links collateral and liquidity to asset prices. [Geanakoplos \(2010\)](#) combines the insights from [Geanakoplos \(1997\)](#) where the collateral is based on non financial assets and [Geanakoplos \(2003\)](#) where the collateral is based on financial assets; and shows that the introduction of CDS contracts reduces

the asset prices. By doing this he puts forward a model of a *double leverage cycle*, in housing and securities, which contributes in the explanation of the 2007-08 crisis. [Fostel and Geanakoplos \(2012\)](#) provide a further analysis of CDS contracts and show: (i) why trenching and leverage initially raised asset prices and (ii) why CDSs lowered them later. [Simsek \(2013a\)](#) considers a continuum of states and two types of agents beliefs, namely optimist and pessimist. He shows that the type of disagreement between agents has more important effects on asset prices than the degree of disagreement between optimists and pessimists.<sup>5</sup> To our knowledge, this is the only paper in this literature which considers the effect of different degrees of heterogeneity<sup>6</sup>

Along similar lines the effects of leverage have been studied by [Gromb and Vayanos \(2002\)](#), [Acharya and Viswanathan \(2011\)](#), [Brunnermeier and Pedersen \(2009\)](#), [Brunnermeier and Sannikov \(2014\)](#) and [Adrian and Shin \(2010\)](#), among others. These approaches differ from the models mentioned in the previous paragraphs in two key aspects. The models of [Acharya and Viswanathan \(2011\)](#), [Adrian and Shin \(2010\)](#), [Brunnermeier and Sannikov \(2014\)](#) and [Gromb and Vayanos \(2002\)](#) focus on the ratio of an agent's total asset value to his total wealth (investor based leverage) while the leverage cycle models of Geanakoplos and coauthors<sup>7</sup> focus on LTV. The second aspect

---

<sup>5</sup>Other works in the leverage cycle literature include [Geanakoplos and Zame \(2014\)](#), [Geanakoplos \(2014\)](#) and [Fostel and Geanakoplos \(2016\)](#). For a recent review of this literature see [Fostel and Geanakoplos \(2014\)](#).

<sup>6</sup>In a different context [Simsek \(2013b\)](#) shows that the level of belief disagreement affects the average consumption risks of individuals in a model which studies the effect of financial innovation on portfolio risks.

<sup>7</sup>Also the models of [Brunnermeier and Pedersen \(2009\)](#), and [Simsek \(2013a\)](#) use the

has to do with the fact that in the models of Brunnermeier and Pedersen (2009) and Gromb and Vayanos (2002) the leverage ratio is exogenously given, where in the former is given by a  $VaR$  rule, whereas in the latter it is given by a maximin rule used to prevent defaults. In the cases of Brunnermeier and Sannikov (2014), Acharya and Viswanathan (2011) and Adrian and Shin (2010) leverage is endogenous but is not determined by collateral capacities. In Acharya and Viswanathan (2011) and Adrian and Shin (2010) leverage is determined by asymmetric information between borrowers and lenders; while in Brunnermeier and Sannikov (2014) it is determined by agents' risk aversion.

### 3. Model

#### 3.1. Environment

We study an economy with two assets, one riskless (cash  $C$ ) and one risky, two types of traders and a bank. The supply of the risky asset, which can be viewed as a stock, is fixed and equal to  $N$ , whereas there is an infinite supply of the riskless asset. The price of the riskless asset is normalised to 1, whereas the price of the risky asset at time  $t$   $p_t$  is determined endogenously. The riskless and the risky asset are traded by a representative, mean-reverting noise trader and  $K$  types of hedge funds (HFs), whose objective is to exploit potential mispricings of the risky asset. The role of the bank, which is infinitely liquid, is to provide credit to HFs, by using the HF's assets as collateral.

**Representative Hedge Fund:** Each HF is run by a myopic portfolio man-

---

same ratio.

ager, whose objective is to maximise her next period's CRRA utility function over his wealth,  $W_t$ :

$$U(W_t^j) = W_t^{j1-\alpha} / (1 - \alpha), \quad (1)$$

where  $\alpha > 0$  is the measure of relative risk aversion, and  $j \in \{1, \dots, K\}$ .

The manager's strategy of the  $j$ th HF is a mapping from her information set  $S^j$  to trading orders for the risky and the riskless asset, where  $D_t^j$  ( $C_t^j$ ) denotes the units of the risky (riskless) asset the  $j$ th HF is willing to trade. Thus, beliefs about the mean logarithmic price of the risky asset  $\mathbb{E}[\log(p_{t+1})]$  and the volatility  $\text{Var}[\log p_{t+1}]$  plays a crucial role in determining orders.

We assume that only part  $(1 - \gamma)$  of the current wealth of the HF is available for re-investment in the next period. The purpose of this assumption is to exclude unrealistic cases where the wealth of HF's explodes and default never occurs.<sup>8</sup> This assumption could be interpreted in multiple ways. For instance, it is consistent with the empirical evidence indicating that the compensation of the fund managers is tied to the wealth of the HF. This evidence is also in line with the theoretical literature on optimal contracting in principal-agent environments. Alternatively, the share  $\gamma$  which is not re-invested could be capturing the HF investors' payment. Taking this into account the wealth of a HF evolves according to:

$$W_{t+1}^j = (1 - \gamma)W_t^j + (p_{t+1} - p_t)D_t^j, \quad (2)$$

---

<sup>8</sup>It is worth highlighting that assuming that the share of wealth which is not re-invested is fixed and constant over time, allows us to develop a more tractable model. However, the critical component for our main findings to go through is that not all wealth is re-invested.

where the first term of the RHS captures the value of the portfolio held in the previous period, and the second term captures the change in the value of the risky assets.

It is worth highlighting that the amount of cash required to complement the trading order for a risky asset, i.e.,  $D_t^j p_t$ , may exceed the cash which is available at the beginning of each trading period. This can be the case because we allow for access to credit. However, this access to credit is not unbounded, and is assumed to be subject to regulation. Here the HF cannot become more leveraged than  $\lambda_{max}$ , a maximum ratio of the market value of the risky asset held as collateral by the bank to the net wealth of the risky asset. Thus, the maximum leverage constraint translates into:

$$D_t^j p_t / W_t^j \leq \lambda_{max}.$$

Consequently, the maximum demand for the risky asset is given by:

$$D_{t,max} = \lambda_{max} W_t^j / p_t, \quad \forall j \in \{1, \dots, K\}. \quad (3)$$

Furthermore, we allow the HFs to take only long positions, i.e., to be active only when the asset is underpriced<sup>9</sup>.

**Default:** We define as default any event in which the wealth of a HF falls below  $W_{min} \ll W_0$ , where  $W_0$  denotes the initial endowment of each HF upon entrance in the market. This enables us to endogenise the probability

---

<sup>9</sup>We do this in order to highlight that, even with the HFs taking only long positions, a strategy inherently less risky than short-selling, the clustering of defaults, and thus systemic risk, is still present if heterogeneity among the prior beliefs is sufficiently large.

of default of each HF. The main objective of this paper is to study both the individual (HF) and collective (systemic) default probabilities over time. After  $T_r \sim U[b, c]$ , time-steps the bankrupt HF is replaced by a HF with identical characteristics. This allows us to maintain the character of the market (at a statistical level).

**Noise traders:** The second type of traders is noise-traders, who are supposed to trade for liquidity reasons. Following the related literature, we assume that the demand  $d^{nt}$  of the representative noise-trader for the risky asset, in terms of cash value, is assumed to follow a first-order autoregressive [AR(1)] process (Xiong, 2001; Thurner et al., 2012; Poledna et al., 2014).

$$\log d_t^{nt} = \rho \log d_{t-1}^{nt} + (1 - \rho) \log(VN) + \chi_t, \quad (4)$$

where  $\rho \in (0, 1)$  is a parameter controlling the rate of reverting to the mean. Given that the expected value of  $\chi_t$  and the auto-covariance function are time-independent, the stochastic process is wide-sense stationary,  $\chi_t \sim \mathcal{N}(0, \sigma_{nt}^2)$ , and  $V$  is the fundamental value of the risky asset<sup>10</sup>.

**Trading orders and Equilibrium prices:** Finally, the price of the risky asset is determined endogenously by the market clearing condition [together with Eqs. (2), (4), and (7)]<sup>11</sup>.

$$D_{t+1}^{nt}(p_{t+1}) + \sum_{j=1}^K D_{t+1}^j(p_{t+1}) = N, \quad (5)$$

---

<sup>10</sup>The demand of the noise traders in terms of the number of shares of the risky asset  $D^{nt}$  and the price of the risky asset  $p_t$  at period  $t$  is  $d_t^{nt} = D_t^{nt} p_t$ . Hence, In the absence of the HFs, from Eq. (4), and Eq. (5) we have  $\mathbb{E}[\log p_{t+1}] = \log V$ .

<sup>11</sup>This system of equations is highly non-linear, and thus, can only be solved numerically.

where  $D_{t+1}^{\text{nt}}(p_{t+1}) = d_{t+1}^{\text{nt}}/p_{t+1}$  stands for the demand of the noise traders whereas  $D_{t+1}^j(p_{t+1})$  stands for the demand of the  $j$ th HF. Both values are in number of shares.

**Source of Heterogeneity:** A critical component, which lies at the heart of our analysis, is heterogeneity across HFs. We allow for a setup where different HFs respond differently when facing the same price. In particular, we assume that for a given price  $p_t$ , different HFs post different demand orders of the risky asset, i.e.,  $D_t^i \neq D_t^j$  for  $i \neq j$ . One can think of many cases which could justify heterogeneity across HFs. One explanation could be that HFs have different beliefs about the fundamental value  $V$  of the asset. Another case which could justify this heterogeneity could be that HFs agree on the mean, but they disagree on the variance, i.e.,  $\text{Var}[\log p_{t+1} | \mathcal{F}^j]$ . Finally, HFs' heterogeneity might be driven by different degrees of risk aversion, i.e.,  $\alpha$ . The main findings are qualitatively equivalent independently of which of the previous possible interpretations is implemented. Throughout the paper we assume that HFs disagree on the market volatility.

The rationale behind the assumption that the managers agree on the fundamental value of the asset, but disagree on price volatility, relies on the fact that the fundamental value, as opposed to price volatility, is not affected by the behaviour of HFs. In other words, the fundamental value of the asset is exogenously determined, whereas the volatility of the market is endogenously determined, with its value depending on the HFs' trading strategy, which in turn, depends on their private information set. Hence, it is not feasible for the managers to reach an agreement on the market volatility, because they

have access to different information sets, and the market volatility is affected by the information each manager has access to.

**Timing:** Each period  $t$  consists of 4 sub-periods

1. The managers set their demand orders for the risky asset.
2. The price of the risky asset is determined, and the return of each portfolio is realised.
3. The managers receive their compensation.
4. The next-period's wealth is determined.

### 3.2. Optimal Demand

The manager of the  $j$ th HF maximises his expected utility, given his beliefs  $\mathcal{F}^j$  about the asset's fundamental value and the volatility of the market, and subject to the constraint that the demand cannot exceed  $D_{t,\max}^j$ . This is expressed as

$$D_t^j = \operatorname{argmax}_{D_t^j \in [0, D_{t,\max}^j]} \{ \mathbb{E} [U(W_{t+1}^j) | \mathcal{F}^j] \} \quad (6)$$

Solving the optimisation problem we obtain<sup>12</sup>

$$D_t^j = \min \left\{ \frac{1}{a} \left( s_j \log(V/p_t) + \frac{1}{2} \right), \lambda_{\max} \right\} \frac{W_t^j}{p_t}, \quad (7)$$

where  $s_j = 1/\operatorname{Var}[\log p_{t+1} | \mathcal{F}^j]$ . Therefore, the demand of the HFs is proportional to the expected logarithmic return and their wealth, and inversely proportional to the conditional variance of the logarithm of the price, given their beliefs.

---

<sup>12</sup>For details see Appendix A.

The clustering of HFs' defaults is determined by the decay rate of the of the default time-sequence autocorrelation function (ACF)  $C(t')$ , with  $t'$  being the time-lag variable. If defaults are clustered, then  $C(t')$  decays in such a way that the sum of the ACF over the lag variable diverges (Baillie, 1996; Samorodnitsky, 2006, 2007).

**Definition 1.** Let  $C(t')$  denote the autocorrelation of the time series of defaults, with  $t'$  being the lag variable. Defaults are clustered if and only if

$$\sum_{t'=0}^{\infty} C(t') \rightarrow \infty. \quad (8)$$

Given that the ACF is bounded in  $[-1, 1]$ , it follows that the convergence of the infinite sum is in turn determined by the asymptotic behaviour  $t' \gg 1$  of the ACF. In this limit, the sum can be approximated by an integral.

In the following we assume that the ACF of the default time sequence can be approximated by a continuous function for  $t' \gg 1$ . Then it follows that,

**Remark 1.** Defaults are clustered if the ACF asymptotically approaches zero not faster than  $C(t') \sim 1/t'$ . In this case defaults are interrelated (statistically dependent) for all times.

**Remark 2.** If the decay of the ACF is faster than algebraic, then defaults are not clustered. The effect of the shock caused by the default of a HF on the market is only transient, and the defaults are in the long-run statistically independent.

Our main goal is to study the relationship between the degree of heterogeneity  $\kappa$ , identified with the difference between extreme values of  $s_j$ , and

clustering of defaults. The question arises as to whether the leverage cycle is a sufficient condition for the defaults to be clustered, or rather whether there exists a critical value for the degree of heterogeneity above which the mechanism of the leverage cycle leads to clustering of defaults.

In the next section, we present the results of the model. The first subsection presents the numerical results obtained by iterating the model defined above. We present the ACFs for various values of  $\kappa$  and interpret these in light of Remarks 1 and 2. Section 4.2 provides an analytical insight into the numerical results.

## 4. Results

### *Choice of Parameters*

In all simulations we consider a market with  $K = 10$  HFs. In the following we assume homogeneous preferences towards risk across HFs, and set  $a_j = 3.2 \forall j \in \{1, \dots, 10\}$ , this being a typical value for HFs (Gregoriou et al., 2007, p. 417). From Eq. (4) we have  $\tilde{\sigma}_{\text{nt}}^2 = \sigma_{\text{nt}}^2 / (1 - \rho^2)$ , where  $\rho$  is the mean reversion parameter. The inverse of the expected volatility given the HF's prior beliefs, i.e.  $s_j = 1 / \text{Var} [\log p_{t+1} | \mathcal{F}^j]$  determines the responsiveness of the HFs to the observed mispricing. In our numerical simulations  $s_j$  is sampled from a uniform distribution in  $[1, \delta]$ , and  $\delta \in [1.2, 10]$ .

Moreover, the maximum allowed leverage  $\lambda_{\max}$  is set to 5. This particular value is representative of the mean leverage across HFs employing different strategies (Ang et al., 2011). The remaining parameters are chosen as follows:  $\sigma_{\text{nt}}^2 = 0.035$ ,  $V = 1$ ,  $N = 10^9$ ,  $W_0 = 2 \times 10^6$ ,  $W_{\min} = W_0/10$ ,  $\rho = 0.99$  (Poledna et al., 2014), and  $\gamma = 5 \times 10^{-4}$ . Bankrupt HFs are reintroduced

after  $T_r$  periods, randomly chosen according to a uniform distribution in  $[10, 200]$ . asset is undervalued—will help moderate the fluctuations realised in the market. In other words, all HFs correctly believe that the volatility of the market will be reduced when they enter the market, in comparison to the volatility observed when only the noise traders are active. However, they are uncertain about their collective market power, and therefore the extent to which they will affect the realised volatility. Thus, all HFs believe that  $\mathbb{E}[\text{Var}(\log p_{t+1}) | \mathcal{F}^j] < \sigma_{\text{nt}}^2 / (1 - \rho^2)$ .

#### 4.1. Numerical results

As aforementioned, the leverage cycle consists in the interplay between the variability of prices of the assets put as collateral, and margin requirements. When prices are high, assets used as collateral are overpriced, and creditors are willing to lend. In the face of an abrupt fall of the market price of the assets used as collateral, creditors force the lenders to repay part of the loan, such that the margin requirements are met. Consequently, the lenders are forced to sell in a falling market, accelerating and reinforcing the fall of the price of the collateral, creating thus a vicious cycle.

In our model, a fall in the price of the risky asset used as collateral is caused by a sudden drop of the demand of the noise traders  $d_t^{\text{nt}}$ . This results into a sudden increase of the leverage ratio of the  $j$ th HF,  $\lambda_t^j$ . In case  $\lambda_t^j$  exceeds the margin requirement  $\lambda_t^j \leq \lambda_{\text{max}}^j$  HFs are forced to sell, pushing the price even lower. This is illustrated in Fig. 1, where we present: (a) the wealth of three HFs (under, moderately, and highly responsive to mispricings,  $j = 2, 6, 10$ ) (b) the corresponding leverage ratio (c) the demand of the noise traders, and (d) the price of the risky asset at equilibrium as a function of

time, for a low degree of heterogeneity  $\kappa = \delta - 1 = 0.5$ .

At time  $t = 738$  [marked by a blue triangle in panel (c)] a drop in the demand of the noise-traders causes an underpricing of the risky asset backing up the loans of HFs [panel (d)]. In turn, the leverage ratio of all the HFs depicted in Fig 1(b)  $\lambda_{t=738}$  increases abruptly [panel (b)], and the margin requirement  $\lambda_{\max} = 5$  becomes binding for the most responsive of the HFs depicted ( $j = 6, 10$ ). At this point, the HFs are forced to deleverage pushing the price of the collateral further down, leading all HFs depicted to default [panel (a)]. The pressure on the price of the risky asset due to the synchronous deleveraging of the highly responsive HFs can clearly be recognized if we compare the lowest price reached around the downturn of the leverage cycle at about  $t = 738$  [marked by a the dashed red line in panel (d)], with the equilibrium price at  $t = 7153$  [blue filled circle], where the demand of the noise trader becomes virtually the same to that at  $t = 738$  [marked by a blue triangle], but the price remains at a considerably higher level. This is because the wealth of all HFs in this case, is such that the leverage ratio stays well below the maximum threshold [see panel (b)], and the leverage cycle mechanism remains inactive.

Another observation worth commenting on, is the fact that after the HFs have been reintroduced in the market, we notice that the least responsive HF ( $j = 2$ ), defaults another 2 times, by the end of the time-series depicted in Fig. 1, namely at  $t = 3976$ , and  $t = 9161$  [also marked by blue triangles in panel (a)]. not because of the presence of a shock in the demand of the risky asset, but rather, due to its poor performance. This is because time is costly in our model (HFs pay managerial fees), and if the profitability of a

Figure 1: (a) The wealth normalised by the endowment  $W_0$ , (b) the leverage ratio  $\lambda_t^j$ , (c) the demand of the noise traders in terms of money-value, normalised also by  $W_0$ , and (d) the equilibrium price of the risky asset, as a function of time, in the case of  $\kappa = 0.5$ .

HF is low, then it will inevitably be led to bankruptcy, even in the absence of a shock on the demand of the risky asset. These defaults happen at random times, i.e. when the observed mispricings happen to be small, or when the asset is overpriced, for a period of time, and the profits made are also small, or null, respectively. This also explains the second default of the 6th HF, at  $t = 6618$  [red triangle in Fig. 1(a)], when all the HFs are well below the maximum leverage constraint.

Let us now study an example with a higher degree of heterogeneity. In Fig. 2 we present the wealth  $W_t^j$  [panel (a)], the leverage ratio  $\lambda_t^j$  [panel (b)] of 3 representative HFs [ $j = 2, 6, 10$ ], as well as the logarithmic returns [panel (c)] as a function of time, for  $\kappa = 3$ . At  $t = 493$  [marked by a red circle in panels (a), and (c)] the leverage cycle becomes active, causing an underpricing of the risky asset. However, the least responsive to mispricings hedge fund ( $j = 2$ ) of the three depicted, manages to absorb the shock, as it stays below the maximum leverage  $\lambda_{\max} = 5$  [see panel (b), blue line], and never receives a margin call. However, the bankruptcy of the more responsive HFs, offers the HF that has survived the shock ( $j = 2$ ), the opportunity to seize a larger market share and, as a result, to perform better in the short-run, restoring its wealth to a level similar to the one before the shock occurred. In this way, the most poorly performing HF is given the opportunity to continue operating until the next downturn of the leverage cycle, at which point it defaults along with the rest of the HFs at  $t = 2371$  [red disc]. After the second crash of the market we observe the end of yet another leverage cycle, at which point all the depicted HFs default again in sync at  $t = 3044$  [black disc]. The narrative is repeated once more at  $t = 3684$  [blue circle], when

again the least responsive HF after absorbing the shock gets a larger market share, increasing shortly its profitability.

In conclusion, the study of time-series in the case of low ( $\kappa = 0.5$ ) and high heterogeneity ( $\kappa = 3$ ) reveals that increased heterogeneity leads to the increase of collective defaults. Even more, the synchronous default of highly responsive HFs, gives the opportunity to the less responsive ones to increase their market share, and thus, their profitability, even for a short-period of time. Still, this increases the chance of the poor-performing HFs to survive until the next downturn of the leverage cycle, suppressing defaults occurring at random times due to their poor performance, and thus increasing even more the probability of synchronous defaults. Therefore, this analysis hints that the degree of heterogeneity is intimately connected to the level of systemic risk in the market.

To assess quantitatively the effect of the degree of heterogeneity, explained above, on the systemic risk, we study the persistence of the correlation between defaults [see Definition 1]. In Figure 3(a) we compare the numerically computed ACF of the default time-sequence<sup>13</sup> as observed on the aggregate level for 11 different degrees of heterogeneity  $\kappa$ , determined by the support of the distribution of  $s_j$ . The results were obtained by iterating the model described in Section 3 for up to  $3 \times 10^8$  periods, and averaging over 40 realisations of the responsiveness  $s_j$ ; namely,  $s_j \sim U[1, \delta]$ , with  $\delta = \{1.2, 1.4, 1.7, 2, 3, 5, 6, \dots, 10\}$ . Clearly, when the degree of heterogeneity  $\kappa \leq 1$ , the ACF decays far more rapidly in comparison with larger values

---

<sup>13</sup>The time-sequence considered is constructed by mapping defaults to 1s, irrespective of which HF defaulted, and to 0 otherwise.

Figure 2: (a) The wealth normalised by the endowment  $W_0$ , (b) the leverage ratio  $\lambda_t^j$ , and (d) the logarithmic returns on the risky asset, as a function of time, with  $\kappa = 3$ .

of heterogeneity. In fact, as it can be observed in the figure, the ACF for  $\kappa \leq 1$  decays faster than a power-law with exponent equal to  $-1$  (black dashed line), which is the largest exponent (in absolute terms) leading to a non-integrable ACF [see Remark 1]. On the other hand, the converse is true for large degrees of heterogeneity ( $\kappa > 2$ ), in which case the ACF decays asymptotically— $t' \gg 1$ —as a power-law with exponent less than 1 in absolute value. Consequently,

**Result 1.** For  $\kappa \leq 1$ , the ACF decays faster than a power-law with exponent  $-1$ . Hence, the mechanism of the leverage cycle does not result into sufficiently high long-range correlations for defaults to be clustered.

Figure 3(a) also shows that for increasing heterogeneity the ACF converges to a limiting form as the heterogeneity is increased, which is reflected in the coalescence of the ACFs corresponding to  $\kappa \geq 5$ . The latter is more clearly demonstrated in Fig. 3(b), where a blow-up of the area within the rectangle shown in panel (a) is presented. Therefore,

**Result 2.** For sufficiently large values of the degree of heterogeneity  $\kappa$ , namely for  $\kappa \geq 5$ , the ACF converges to a limiting form exhibiting a power-law trend with an exponent less than 1 (in absolute value).

To gain some insight into the qualitative difference with respect to the persistence of correlations between defaults as a function of the degree of heterogeneity  $\kappa$ , let us turn our attention to the default statistics. In Fig. 4 we present the aggregate PDF of waiting times between defaults<sup>14</sup> using a

---

<sup>14</sup>The PDF of waiting-times between default is also known as the failure function in survival analysis theory.

Figure 3: (a) The ACF of the binary sequence of defaults corresponding to 11 different values of  $\kappa$ . The dashed black line corresponds to a power-law with exponent -1, which is the largest exponent that leads to clustering [see Remark 1].

Figure 3: (b) A blow-up of the rectangular area shown in panel (a) illustrating the coalescence of  $C(t')$  for large values of the degree of heterogeneity,  $\kappa = \{6, 7, 8, 9\}$ . (c) The ACF corresponding to  $\kappa = 9$ , averaged over  $5 \times 10^2$  different realisations of  $s_j$  (red upright triangles). The blue dot-dashed line is the result of fitting  $C(t')$  with a power-law model  $C(t') \propto t'^{-\eta}$ ,  $\eta = 0.887 \pm 0.003$  ( $R^2 = 0.9927$ ). The power-law with exponent  $-1$  is also shown for the sake of comparison (black dashed line).

logarithmic scale on both axes for 6 different values of  $\kappa$ . We observe that for small degrees of heterogeneity  $\kappa = \{0.2, 0.4, 0.7\}$  the density function asymptotically decays approximately exponentially. This is better demonstrated in the inset where we use semi-logarithmic axes<sup>15</sup>. On the contrary, for sufficiently large heterogeneity—such that the corresponding ACFs have converged to the limiting form—the PDFs exhibit a constant decay rate in the doubly logarithmic plot (power-law tail). Fitting the aggregate density for  $\kappa = 9$ <sup>16</sup>, corresponding to the highest degree of heterogeneity considered, with the model  $\tilde{P}(\tau) \sim \tau^{-\zeta}$  we obtain  $\zeta = 2.84 \pm 0.03$  (red dashed line).

Let us now turn our attention to the statistical properties of HFs on a microscopic scale, i.e. study each HF default statistics individually. In Fig. 5 we show as an example the density function  $P_j(\tau)$ , of waiting times  $\tau$  between defaults, for a number of HFs corresponding to high heterogeneity,  $\kappa = 9$ , with  $s_j = \{2, 4, 6, 8, 10\}$  on a log-linear scale. The results were obtained

---

<sup>15</sup>The use of a logarithmic scale for the vertical axis transforms an exponential function to a linear one.

<sup>16</sup>To increase the accuracy of the fit, we increase the number of realisations of  $s_j$  to  $10^3$ .

Figure 4: The aggregate PDF of waiting times between defaults for 6 different degrees of heterogeneity using double logarithmic scale. For large heterogeneity  $\kappa = \{7, 8, 9\}$ , we observe that the PDF is decaying approximately linearly, corresponding to a power-law decay. Performing a fit with the model  $\tilde{P}(\tau) \sim \tau^{-\zeta}$  we obtain  $\zeta = 2.84 \pm 0.03$  ( $R^2 = 0.9947$ ). To illustrate the approximate exponential asymptotic decay of the aggregate PDF for  $\kappa = \{0.2, 0.4, 0.7\}$  we also show the corresponding aggregate densities using a logarithmic scale on the vertical axis (inset).

by iterating the model for  $3 \times 10^8$  periods and averaging over 100 different initial conditions<sup>17</sup>, holding  $s_j$  fixed at  $\{1, 2, \dots, 10\}$ . We observe that  $P_j(\tau)$  for  $\tau \gg 1$  decays linearly, and thus it can be well described by an exponential function.

Figure 5: The PDF of waiting times between defaults  $\tau$  for specific HFs, having different responsiveness  $s_j = \{2, 4, 6, 8, 10\}$  (black diagonal crosses, downright triangles, red upright crosses, magenta diamonds and cyan upright triangles, respectively). Note the log-linear scale.

<sup>17</sup>We are averaging using different seeds for the pseudo-random number generator used in Eq. (4).

Consequently, all HFs on a microscopic level—individually—are characterised by exponential PDFs of waiting-times, and therefore the default events approximately follow a Poisson process. The stability of each HF, quantified by the probability of default per time-step  $\mu_j$ , is different for each HF, and depends on its responsiveness  $s_j$ . This is reflected by the different slopes of the approximately straight lines shown in Fig. 5 for the different values of  $s_j$ .

Thus, the default statistics on an aggregate level are qualitatively different for large values of  $\kappa$  compared to the corresponding ones observed when each HF is studied individually. Moreover we have already established that for such high values of the degree of heterogeneity the defaults are clustered. In the following we will investigate how the emergence of a fat-tail in the aggregate statistics is connected with the observed clustering of defaults.

#### 4.2. Analytical Results

From the numerical results, we observe that  $P_j(\tau)$ , for  $\tau \gg 1$  decays linearly (in log- linear scale) and thus it can be well described by an exponential function. Therefore we can assume that:

$$P_j(\tau; \tau \gg 1) \sim \mu_j \exp(-\mu_j \tau), \quad \forall j \in \{1, \dots, 10\}. \quad (9)$$

When the above is true, we know that for sufficiently long waiting times between defaults; default events of individual HFs have the following statistical properties: (i) they are approximately independent and (ii) occur with a well defined mean probability per unit time step. From this we get that the probability  $P_j(T = \tau)$ ,  $\tau \in \mathbb{N}_+$ , is given by a geometric probability mass

function (PMF)

$$P_j(\tau) = p_j(1 - p_j)^{\tau-1}, \quad (10)$$

where  $p_j$  denotes the probability of default of the  $j$ th HF.

Given that our focus is in the asymptotic properties of the PDFs,  $T$  can be treated as a continuous variable. In this limit, the renewal process given by equation (10), becomes a Poisson process; and the geometric PMF tends to an exponential PDF<sup>18</sup>. Thus equation (9) can be approximated by equation (10).

The question then arises as to how the aggregation of these very simple stochastic processes can lead to the non-trivial fat-tailed statistics we observed in Fig. 4 for a sufficiently high degree of heterogeneity. Evidently, the aggregate PDF  $\tilde{P}(\tau)$  we seek to obtain is a result of the mixing of the Poisson processes governing each of the HFs. In the limit of a continuum of HFs the aggregate distribution is

$$\tilde{P}(\tau) = \int_0^\infty \mu \exp(-\mu\tau) \rho(\mu) d\mu, \quad (11)$$

where  $\rho(\mu)$  stands for the PDF of  $\mu$  given the responsiveness  $s_j$ <sup>19</sup>.

**Assumption 1.**  $\rho(\mu)$  in a neighbourhood of 0 can be expanded in a power series of the form  $\rho(\mu) = \mu^\nu \sum_{k=0}^n c_k \mu^k + R_{n+1}(\mu)$ , with  $\nu > -1$ <sup>20</sup>.

---

<sup>18</sup>This limit is valid for  $\tau \gg 1$  and  $p_j \ll 1$  such that  $\tau p_j = \mu_j$ , where  $\mu_j$  is the parameter of the exponential PDF [see equation (9)] (Nelson, 1995).

<sup>19</sup>The distribution function of the random parameter  $\mu$  is also known as the *structure* or *mixing* distribution (Beichelt, 2010).

<sup>20</sup>Since  $\rho(\mu)$  is a PDF it must be normalisable and thus, a singularity at  $\mu = 0$  must be integrable.

This assumption is quite general, and only excludes functions that behave pathologically in a neighbourhood around 0. Then from equation (9) and Assumption 1 we can show that the aggregation of the exponential densities determining the default statistic for each HF individually leads to a qualitatively different heavy-tailed PDF.

Let  $\mu^j \in \mathbb{R}^+$  be the mean default rate of the  $j$ th HF, contributing at the aggregate level with a statistical weight  $\rho(\mu)$ , which is determined by the interactions between the agents in the market and the distribution of the responsiveness  $s$ .

**Proposition 1.** *Consider the exponential density function  $P(\tau; \mu)$  describing the individual default statistics of a HF. It follows then from Assumption 1, that the aggregate PDF  $\tilde{P}(\tau)$  exhibits a power-law tail.*

PROOF. The aggregate density can be viewed as the Laplace transform  $\mathcal{L}[\cdot]$  of the function  $\phi(\mu) \equiv \mu\rho(\mu)$ , with respect to  $\mu$ . Hence,

$$\tilde{P}(T = \tau) \equiv \mathcal{L}[\phi(\mu)](\tau) = \int_0^\infty \phi(\mu) \exp(-\mu\tau) d\mu. \quad (12)$$

To complete the proof we apply Watson's Lemma (Debnath and Bhatta, 2007, p. 171) to the function  $\phi(\mu)$ , according to which the asymptotic expansion of the Laplace transform of a function  $f(\mu)$  that admits a power-series expansion in a neighbourhood of 0 [see Assumption 1] of the form  $f(\mu) = \mu^\nu \sum_{k=0}^n b_k \mu^k + R_{n+1}(\mu)$ , with  $\nu > -1$  is

$$\mathcal{L}_\mu[f(\mu)](\tau) \sim \sum_{k=0}^n b_k \frac{\Gamma(\nu + k + 1)}{\tau^{\nu+k+1}} + O\left(\frac{1}{\tau^{\nu+n+2}}\right). \quad (13)$$

Given that  $\phi(\mu)$  for  $\mu \rightarrow 0_+$  is

$$\phi(\mu) = \mu^{\nu+1} \sum_{k=0}^n c_k \mu^k + R_{n+1}(\mu), \quad (14)$$

we conclude that

$$\tilde{P}(\tau) \propto \frac{1}{\tau^{k+\nu+2}} + O\left(\frac{1}{\tau^{k+\nu+3}}\right). \quad (15)$$

**Corollary 1.** *If  $0 < k + \nu \leq 1$ , then the variance of the aggregate density diverges (shows a fat tail). However, the expected value of  $\tau$  remains finite.*

An important aspect of the emergent heavy-tailed statistics stemming from the heterogeneous behaviour of the HFs, is the absence of a characteristic time-scale for the occurrence of defaults (scale-free asymptotic behaviour<sup>21</sup>). Thus, even if each HF defaults according to a Poisson process with intensity  $\mu(s)$ —which has the intrinsic characteristic time-scale  $1/\mu(s)$ —after aggregation this property is lost due to the mixing of all the individual time-scales. Therefore, on a macroscopic level, there is no characteristic time-scale, and all time-scales, short and long, become relevant.

This characteristic becomes even more prominent if the density function  $\rho(\mu)$  is such that the resulting aggregate density becomes fat-tailed, i.e. the variance of the aggregate distribution diverges. In this case extreme values of waiting times between defaults will be occasionally observed, deviating far

---

<sup>21</sup>If a function  $f(x)$  is a power-law, i.e.  $f(x) = cx^a$ , then a rescaling of the independent variable of the form  $x \rightarrow bx$  leaves the functional form invariant ( $f(x)$  remains a power-law). In fact, a power-law functional form is a necessary and sufficient condition for scale invariance (Farmer and Geanakoplos, 2008). This scale-free behaviour of power-laws is intimately linked with concepts such as self-similarity and fractals (Mandelbrot, 1983).

from the mean. This will leave a particular “geometrical” imprint on the sequence of default times. Defaults occurring close together in time (short waiting times  $\tau$ ) will be clearly separated due to the non-negligible probability assigned to long waiting times. Consequently, defaults, macroscopically, will have a “bursty” or intermittent, character, with long quiescent periods of time without the occurrence of defaults and “violent” periods during which many defaults are observed close together in time. Hence, infinite variance of the aggregate density will result in the clustering of defaults.

In order to show this analytically, we construct a binary sequence by mapping time-steps when no default events occur to 0 and 1 otherwise. As we show below, if the variance of the aggregate distribution is infinite, then the autocorrelation function of the binary sequence generated in this manner, exhibits a power-law asymptotic behaviour with an exponent  $\beta < 1$ . Therefore, the ACF is non-summable and consequently, according to Definition 1 defaults are clustered.

Let  $T_i, i \in \mathbb{N}_+$ , be a sequence of times when one or more HF's default and assume that the PDF of waiting times between defaults  $\tilde{P}(\tau)$ , for  $\tau \rightarrow \infty$ , behaves (to leading order) as  $\tilde{P}(\tau) \propto \tau^{-a}$ . Consider now the renewal process  $S_m = \sum_{i=0}^m T_i$ . Let  $Y(t) = 1_{[0,t]}(S_m)$ , where  $1_A : \mathbb{R} \rightarrow \{0, 1\}$  denotes the indicator function, satisfying

$$1_A = \begin{cases} 1 & : x \in A \\ 0 & : x \notin A \end{cases}$$

**Theorem 2.** *If the variance of the density function  $\tilde{P}(\tau)$  diverges, i.e.  $2 < a \leq 3$ , then the ACF of  $Y(t)$ ,*

$$C(t') = \frac{\mathbb{E}[Y_{t_0} Y_{t_0+t'}] - \mathbb{E}[Y_{t_0}] \mathbb{E}[Y_{t_0+t'}]}{\sigma_Y^2},$$

where  $t_0, t' \in \mathbb{R}$  and  $\sigma_Y^2$  is the variance of  $Y(t)$ , for  $t \rightarrow \infty$  decays as

$$C(t') \propto t'^{2-\alpha} \quad (16)$$

PROOF. Assuming that the process defined by  $Y(t)$  is ergodic we can express the autocorrelation as,

$$C(t') \propto \lim_{K \rightarrow \infty} \frac{1}{K} \sum_{t=0}^K Y_t Y_{t+t'}. \quad (17)$$

Obviously, in equation (17) for  $Y_t Y_{t+t'}$  to be non-zero, a default must have occurred at both time  $t$  and  $t'$ <sup>22</sup>. The PDF  $\tilde{P}(\tau)$  can be viewed as the conditional probability of observing a default at period  $t$  given that a default has occurred  $t-\tau$  periods earlier. If we further define  $C(0) = 1$  and  $\tilde{P}(0) = 0$ , the correlation function can then be expressed in terms of the aggregate density as follows:

$$C(t') = \sum_{\tau=0}^{t'} C(t' - \tau) \tilde{P}(\tau) + \delta_{t',0}, \quad (18)$$

where  $\delta_{t',0}$  is the Kronecker delta. Since we are interested in the long time limit of the ACF we can treat time as a continuous variable and solve equation (18) by applying the Laplace transform  $\mathcal{L}\{f(\tau)\}(s) = \int_0^\infty f(\tau) \exp(-s\tau) d\tau$ , utilising also the convolution theorem. Taking these steps we obtain

$$C(s) = \frac{1}{1 - \tilde{P}(s)}, \quad (19)$$

where  $\tilde{P}(s) = \int_0^\infty \tilde{P}(\tau) \exp(-s\tau) d\tau$ , since  $\tilde{P}(0) = 0$ . After the substitution of the Laplace transform of the aggregate density in equation (19), one can

---

<sup>22</sup>A detailed exposition of the proof is given in Appendix 5.

easily derive the correlation function in the Fourier space  $\mathcal{F}\{C(t')\}$  by the use of the identity (Jeffrey and Zwillinger, 2007, p. 1129),

$$\mathcal{F}\{C(t')\} \propto C(s \rightarrow 2\pi if) + C(s \rightarrow -2\pi if). \quad (20)$$

to obtain ,

$$\mathcal{F}\{C(t')\} \stackrel{f \ll 1}{\propto} \begin{cases} f^{a-3}, & 2 < a < 3 \\ |\log(f)|, & a = 3 \\ \text{const.}, & a > 3 \end{cases} . \quad (21)$$

Therefore, for  $a > 3$  this power spectral density function is a constant and  $Y_t$  behaves as white noise. Consequently, if the variance of  $\tilde{P}(\tau)$  is finite, then  $Y_t$  is uncorrelated for large values of  $t'$ .

Finally, inverting the Fourier transform when  $2 < a \leq 3$  we find that the autocorrelation function asymptotically ( $t' \gg 1$ ) behaves as

$$C(t') \propto t'^{2-a}, \quad 2 < a \leq 3. \quad (22)$$

Turning back to the numerical results shown in Fig. 4, the aggregate PDF as already discussed converges to a limiting form, characterised by a fat-tail with an exponent equal  $-2.84 \pm 0.03$ . Therefore, from equation (22) we deduce that the ACF should show a power-law trend with exponent  $-0.84 \pm 0.03$ . The result of the regression of the ACF for  $\kappa = 9$  was  $-0.887 \pm 0.003$  [blue dashed-dotted line in Fig. 3(c)], in good agreement with the analytical result.

In this Section we have shown that when the default statistics of HFs are individually described by (different) Poisson processes (due to the heterogeneity in the prior beliefs among the HFs) we obtain a qualitatively different result after aggregation: the aggregate PDF of the waiting-times

between defaults exhibits a power-law tail for long waiting-times. As shown in Proposition 1, if the relative proportion of very stable HFs approaches 0 sufficiently slowly (at most linearly with respect to the individual default rate  $\mu$ , as  $\mu \rightarrow 0$ ), then long waiting-times between defaults become probable, and as a result, defaults which occur closely in time will be separated by long quiescent time periods and defaults will form clusters. The latter is quantified by the non-integrability of the ACF of the sequence of default times, signifying infinite memory of the underlying stochastic process describing defaults on the aggregate level. It is worth commenting on the fact that the most stable (in terms of defaults) HFs are responsible for the appearance of a fat-tail in the aggregate PDF.

## 5. Conclusions

This paper studied the role of the heterogeneity in available information among different HFs in the emergence of clustering of defaults. The economic mechanism leading to the clustering of defaults is related to the leverage cycle put forward by Geanakoplos and coauthors. In these models the presence of leverage in a market leads to the overpricing of the collateral used to back-up loans during a boom, whereas, during a recession, collateral becomes depreciated due to a synchronous de-leveraging compelled by the creditors. In the present work we have shown that this feedback effect between market volatility and margin requirements is a necessary, yet not a sufficient condition for the clustering of defaults and, in this sense, the emergence of systemic risk.

We have shown that a large difference in the expectations of the HFs is an essential ingredient for defaults to be clustered. We show that when the

degree of heterogeneity (realised in our model in terms of the beliefs across HFs about the volatility of the market) is sufficiently high, poorly performing HFs are able to absorb shocks caused by fire-sales. As a result, they obtain a larger than usual market share, and improve their performance. In this fashion, a default due to their poor performance is delayed, allowing them to remain in operation until the downturn of the next leverage cycle. This leads to the increase of the probability of poorly and high-performing hedge funds to default in sync at a later time, and thus the probability of collective defaults.

This manifests itself in the emergence of heavy-tailed (scale-free) statistics on the aggregate level. We show, that this scale-free character of the aggregate survival statistics, when combined with large fluctuations of the observed waiting-times between defaults, i.e. infinite variance of the corresponding aggregate PDF, leads to the presence of infinite memory in the default time sequence. Consequently, the probability of observing a default of a HF in the future is much higher if one (or more) is observed in the past, and as such, defaults are clustered.

Interestingly, a slow-decaying PDF of waiting-times, which inherently signifies a non-negligible measure of extremely stable HFs, is shown to be directly connected with the presence of infinite memory. Therefore, our work shows that individual stability can lead to market-wide risk.

The leverage cycle theory correctly emphasises the importance of collateral, in contrast to the conventional view, according to which the interest rate completely determines the demand and supply of credit. However, the feedback loop created by the volatility of asset prices and margin constraints

poses a systemic risk only if the market is sufficiently heterogeneous such that “pessimistic” players, who individually are very stable, exceed a critical mass.

This work raises several interesting questions, which we aim to address in the future. In this paper we have assumed that the difference in beliefs is due to disagreement about the long-run volatility of the risky asset, and remains constant over time, i.e. the agents do not update their beliefs given their observations. This assumption is crucial in order to be able to analyse the effects of different degrees of heterogeneity. Regarding this issue, future work can take two different directions: On the one hand, this assumption can be relaxed, allowing agents to update their beliefs on market volatility. However, given that market volatility is endogenous, it is not guaranteed that agents’ beliefs will converge. On the other hand, we can study the effects of heterogeneity stemming from different aversion to risk among the HFs, while retaining the common prior assumption. Furthermore, these two approaches can be combined by assuming both different aversion to risk, and different beliefs about price volatility. Finally, our work can also be extended in two further directions. The first being to give a more active role to the bank which provides loans, while the second is to study the effects of different regulations on credit supply.

## Appendix A: Optimal Demand

We seek to determine the optimal demand for each of the HFs given their beliefs about price volatility  $\mathcal{F}^j$ . This translates into the optimisation problem, assuming log-normal returns on the risky asset

$$\operatorname{argmax}_{D_t^j \in [0, D_{t, \max}]} \left\{ \mathbb{E} [U(W_{t+1}^j) | q_j] \right\}, \quad (.1)$$

where  $U(W_{t+1}^j) = W_{t+1}^{j \cdot 1-a} / (1-a) \sim W_{t+1}^{j \cdot 1-a}$ , and  $W_{t+1}^j$  is the wealth of the  $j$ th HF at the next period. To simplify the notation, in the following we will assume that the expected value, and variance are always conditioned on HF's prior beliefs, and moreover, we will drop the superscript  $j$ . Eq. (.1) is equivalent to the maximisation of the logarithm of the expected utility. Furthermore, given that returns are log-normally distributed, it follows that (Campbell and Viceira, 2002, pp. 17-21)

$$\log \mathbb{E} [W_{t+1}^{1-a}] = \mathbb{E} [\log W_{t+1}^{1-a}] + \frac{\operatorname{Var} [\log W_{t+1}^{1-a}]}{2} \quad (.2)$$

Consequently, the problem becomes

$$\operatorname{argmax}_{D_t \in [0, D_{t, \max}]} \left\{ (1-a) \mathbb{E} [\log W_{t+1}] + (1-a)^2 \frac{\operatorname{Var} [\log W_{t+1}]}{2} \right\}. \quad (.3)$$

The wealth of the  $j$ th HF at the next period is

$$W_{t+1} = (1-\gamma)(1+x_t R_{t+1})W_t, \quad (.4)$$

where  $x$  is the fraction of its wealth invested into the risky asset, and  $R$  the (arithmetic) return of the portfolio. Re-expressing Eq. (.4) in terms of the logarithmic returns  $r$  we get

$$\log(W_{t+1}) = \log W_t + \log [1 + x_t (\exp(r_{t+1}) - 1)] + \log(1-\gamma), \quad (.5)$$

albeit a transcendental equation with respect to  $r$ . An approximative solution can be obtained by performing a Taylor expansion of Eq (.5) with respect to  $r$  to obtain

$$\log(W_{t+1}) = \log(W_t) + x_t r_{t+1} \left(1 + \frac{r_{t+1}}{2}\right) - \frac{x_t^2}{2} r_{t+1}^2 + \log(1-\gamma) + \mathcal{O}(r^3). \quad (.6)$$

Substituting Eq. (.6) into Eq. (.3), and furthermore approximating  $\mathbb{E}(r_{t+1}^2)$  with  $\text{Var}(r_{t+1})$  we obtain

$$\underset{D_t \in [0, \lambda_{\max}]}{\operatorname{argmax}} \left\{ \log W_t + x_t \mathbb{E}(r_{t+1}) + \frac{x_t}{2} (1 - x_t) \text{Var}(r_{t+1}) + \log(1 - \gamma) \right\}. \quad (.7)$$

Finally the first-order condition yields

$$x_t = \min \left[ \frac{\mathbb{E}(r_{t+1}) + \frac{1}{2} a \text{Var}(r_{t+1})}{a \text{Var}(r_{t+1})}, \lambda_{\max} \right]. \quad (.8)$$

Consequently, the optimal demand for HF  $j$  in terms of the number of shares of the risky asset given the price at the current period is

$$D_t = \min \left\{ \frac{\log(V/p_t) + \frac{1}{2} a \text{Var}[\log p_{t+1} | \mathcal{F}^j]}{a \text{Var}[\log p_{t+1} | \mathcal{F}^j]}, \lambda_{\max} \right\} \frac{W_t}{p_t}. \quad (.9)$$

## Appendix B: Proof of Theorem 2

As already stated in Section 4.2, Theorem 2, assuming that the process defined by  $Y(t) = 1_{[0,t]}(S_m)$  is ergodic, the auto-correlation function can be expressed as a time-average

$$C(t') \propto \lim_{K \rightarrow \infty} \frac{1}{K} \sum_{t=0}^K Y_t Y_{t+t'}. \quad (.1)$$

Given that  $Y(t)$  is by definition a binary variable, the only non-zero terms contributing to the sum appearing on the right hand side (RHS) of equation (.1) correspond to default events (mapped to 1) that occur with a time difference equal to  $t'$ . Therefore, the RHS of equation (.1) is proportional to the conditional probability of observing a default at time  $t'$ , given that a default has occurred at time  $t = 0$ . Therefore, we can express  $C(t')$  in terms of the aggregate probability  $\tilde{P}(\tau = t')$ , i.e. the probability of a default event being observed after  $t'$  time-steps, given that one has just been observed. Moreover, we must take into account all possible combinations of defaults happening at times  $t < t'$ . For example, let us assume that we want to calculate  $C(t' = 2)$ . In this case there are exactly 2 possible set of events that would give a non-zero contribution. Either a default happening exactly 2 time-steps after the last one (at  $t = 0$ ), or two subsequent defaults happening at  $t = 1$ , and  $t = 2$ . In this fashion, we can express the correlation function in terms of the probability the waiting-times between defaults as ([Procaccia](#)

and Schuster, 1983),

$$C(1) = \tilde{P}(1), \quad (.2)$$

$$\begin{aligned} C(2) &= \tilde{P}(2) + \tilde{P}(1)\tilde{P}(1) \\ &= \tilde{P}(2) + \tilde{P}(1)C(1), \end{aligned} \quad (.3)$$

$\vdots$

$$C(t') = \tilde{P}(t') + \tilde{P}(t' - 1)C(1) + \dots \tilde{P}(1)C(t' - 1). \quad (.4)$$

If we further define  $C(0) = 1$  and  $\tilde{P}(0) = 0$ , then equation (.4) can be written more compactly as

$$C(t') = \sum_{\tau=0}^{t'} C(t' - \tau)\tilde{P}(\tau) + \delta_{t',0}, \quad (.5)$$

where  $\delta_{t',0}$  is the Kronecker delta.

We are interested only in the long time limit of the ACF. Hence, we can treat time as a continuous variable and solve equation (.5) by applying the Laplace transform  $\mathcal{L}\{f(\tau)\}(s) = \int_0^\infty f(\tau) \exp(-s\tau)d\tau$ , utilising also the convolution theorem. Taking these steps we obtain

$$C(s) = \frac{1}{1 - \tilde{P}(s)}, \quad (.6)$$

where  $\tilde{P}(s) = \mathcal{L}\{\tilde{P}(\tau)\}(s) = \int_0^\infty \tilde{P}(\tau) \exp(-s\tau)d\tau$ . We will assume that  $\tilde{P}(\tau) \propto \tau^{-a}$  for any  $\tau \in [1, \infty)$ , i.e. the asymptotic power-law behaviour ( $\tau \gg 1$ ) will be assumed to remain accurate for all values of  $\tau$ . Under this assumption,

$$\tilde{P}(\tau) = \begin{cases} A\tau^{-a}, & \tau \in [1, \infty), \\ 0, & \tau \in [0, 1). \end{cases}, \quad (.7)$$

where  $A = 1/\int_1^\infty \tau^{-a} d\tau = a - 1$ . The Laplace transform of equation (.7) is,

$$\tilde{P}(s) = (a - 1)E_a(s), \quad (.8)$$

where  $E_a(s)$  denotes the exponential integral function defined as,

$$E_a(s) = \int_1^\infty \exp(-st) t^{-a} dt \quad /; \text{Re}(s) > 0. \quad (.9)$$

The inversion of the Laplace transform after the substitution of equation (.8) in equation (.6) is not possible analytically. However, we can easily derive the correlation function in the Fourier space (known as the power spectral density function)  $\mathcal{F}\{C(t')\}(f) = \sqrt{\frac{2}{\pi}} \int_0^\infty C(t') \cos(2\pi f t') dt'$  by the use of the identity (Jeffrey and Zwillinger, 2007, p. 1129),

$$\mathcal{F}\{C(t')\} = \frac{1}{\sqrt{2\pi}} [C(s \rightarrow 2\pi i f) + C(s \rightarrow -2\pi i f)]. \quad (.10)$$

relating the Fourier cosine transform  $\mathcal{F}\{g(t)\}(f)$ , of a function  $g(t)$ , to its Laplace transform  $g(s)$ , to obtain,

$$C(f) = \frac{1}{\sqrt{2\pi}} \left( \frac{1}{1 - (a - 1)E_a(2if\pi)} + \frac{1}{1 - (a - 1)E_a(-2if\pi)} \right) \quad (.11)$$

From equation (.11) we can readily see that as  $f \rightarrow 0_+$  (equivalently  $t' \rightarrow \infty$ ),  $C(f) \rightarrow \infty$ . To derive the asymptotic behaviour of  $C(f)$  we expand about  $f \rightarrow 0_+$  (up to linear order) using

$$E_a(2if\pi) = ai^{a+1}(2\pi)^{a-1}f^{a-1}\Gamma(-a) - \frac{2i\pi f}{a-2} + \frac{1}{a-1} + O(f^2) \quad (.12)$$

to obtain

$$C(f) = -\frac{i\sqrt{2\pi}(a-2)f}{4\pi^2(a-1)f^2 + (2^{a+1}\pi^a(if)^a - a(2i\pi)^a f^a)\Gamma(2-a)} + \frac{i\sqrt{2\pi}(a-2)f}{4\pi^2(a-1)f^2 + (2^{a+1}\pi^a(-if)^a - a(-2i\pi)^a f^a)\Gamma(2-a)}. \quad (.13)$$

After some algebraic manipulation, for  $f \rightarrow 0$  equation (.13) yields

$$C(f) = Af^{a-3}, \quad (.14)$$

where

$$A = -\frac{2^{a+\frac{1}{2}}(a-2)^2\pi^{a-\frac{3}{2}}\sin\left(\frac{\pi a}{2}\right)\Gamma(1-a)}{(a-1)}. \quad (.15)$$

Therefore, for  $2 < a < 3$  we see that the Fourier transform of the correlation function behaves as,

$$C(f) \propto f^{a-3}. \quad (.16)$$

If  $a = 3$ , then the instances of the Gamma function appearing on the RHS of equation (.13) diverge. Therefore, for  $a = 3$  we need to use a different series expansion around  $f \rightarrow 0_+$ . Namely,

$$E_3(2\pi if) = \frac{1}{2} - 2i\pi f + \pi^2 f^2(2\log(2i\pi f) + 2\gamma - 3) + O(f^5), \quad (.17)$$

where  $\gamma$  stands for the Euler's constant. The substitution of equation (.17) into equation (.11) leads to

$$\begin{aligned} C(f) = -\operatorname{Re} \left\{ [2\log(\pi f) - 2\gamma + 3 - \log(4)] / [\sqrt{2\pi}(2i\pi f \log(\pi f) \right. \\ \left. + \pi f(2i\gamma + \pi + i(\log(4) - 3)) - 2) \right. \\ \left. \times (\pi(3i - 2i\gamma + \pi)f - 2i\pi f \log(2\pi f) - 2)] \right\}, \end{aligned} \quad (.18)$$

and thus,

$$\begin{aligned}
C(f) = & \left( -8\gamma^3\pi^2 f^2 - 2\pi^2 f(f(-6\log(\pi)(\log(16\pi^3)) \right. \\
& - 2\gamma \log(4\pi f^2)) + (12\gamma^2 + \pi^2) \log(\pi f) + 9(3 - 4\gamma) \log(2\pi f)) \\
& + 4f \log^3(f) + 6f(2\gamma - 3 + \log(4) + 2\log(\pi)) \log^2(f) \\
& + 6f(\gamma \log(16) + (\log(2\pi) - 3) \log(4\pi^2)) \log(f) + 4f \log(2\pi)((\log(2) - 3) \log(2) \\
& + \log(\pi) \log(4\pi)) - 4\log(2\pi f)) - 4\gamma^2\pi^2 f^2(\log(64) - 9) - 2\gamma(\pi^2 f(f(\pi^2 + 27 + 12\log^2(2)) \\
& - 4) + 4) + \pi^2 f(f(27 - \pi^2(\log(4) - 3) + \log(8) \log(16))) - 12) - 8\log(2\pi f) + 12 \Big) \\
& \Big/ \left( \sqrt{2\pi}(4\pi^2 f^2 \log(\pi f)(\log(4\pi f) + 2\gamma - 3) + \pi^2 f(f(4\gamma^2 + \pi^2 + (\log(4) - 3)^2 \right. \\
& \left. + 4\gamma(\log(4) - 3)) - 4) + 4)^2 \right).
\end{aligned} \tag{.19}$$

As  $f \rightarrow 0$  we have,

$$C(f) \sim |\log(f)| \tag{.20}$$

Finally, if  $a > 3$ , then equation (.11) for  $f \rightarrow 0$  tends to a constant, and thus,  $Y_t$  behaves as white noise. Consequently, if the variance of  $\tilde{P}(\tau)$  is finite, then  $Y_t$  is for large values of  $t'$  is uncorrelated.

To summarise, the spectral density function for  $f \ll 1$  is,

$$C(f) \stackrel{f \ll 1}{\propto} \begin{cases} f^{a-3}, & 2 < a < 3 \\ |\log(f)|, & a = 3 \\ \text{const.}, & a > 3 \end{cases} . \tag{.21}$$

The inversion of the Fourier (cosine) transform in equation (.21) yields,

$$C(t') \propto t'^{2-a}; \quad 2 < a \leq 3 \wedge t' \gg 1. \tag{.22}$$
